Abstract

The crystal structure of albite from Tiburon, Marin County, California, has been refined from three-dimensional X-ray intensity data collected on an automatic single-crystal diffractometer at 500, 750, and 970°C (all $\pm 10^\circ\text{C}$) to *R* factors of 0.032, 0.035, and 0.039 for 1980, 1990, and 2002 reflections respectively. The vibrational amplitude of the sodium atom exhibits a linear dependence on temperature and extrapolates to zero at 0 K within error limits, implying that the high anisotropy of the electron-density distribution about the Na position is strictly a result of anisotropic thermal motion. Structural adjustments to thermally induced stresses are principally associated with *T-O-T* angles as opposed to distortion within the aluminosilicate tetrahedra. Whereas Na-O bond lengths increase substantially with increasing temperature, the *T-O* bond lengths show little change. The apparent slight shortening of the *T-O* bonds is attributed to errors in bond-length calculation caused by thermal motion.

Introduction

The electron density at the sodium atom position in both high and low albite is markedly anisotropic, the effect being much larger in high albite. The anisotropy of the sodium atom has been discussed by Ferguson *et al.* (1958), Williams and Megaw (1964), and Smith (1974). Two possible explanations for this phenomenon are: (1) a time average of highly anisotropic thermal vibration of sodium within the aluminosilicate cage; or (2) a space average of multiple positions occupied by the sodium atom. Multiple positions may occur in either of two ways. There may be two or more positions of low potential energy with sodium atoms occupying different ones or oscillating between them. Another possibility is the existence of a multipartite structure of fault-bounded domains.

Distinguishing between a time average and a space average using electron-density maps can be quite difficult, since the separation of the two positions must be large enough to show up as two distinct peaks. If the separation is smaller than some critical distance, the overlap will appear as a single elongated peak. This problem has been discussed in some detail by

Megaw in an appendix to Ribbe *et al.* (1969). A superior approach is to observe the behavior of the Na atom at a variety of temperatures. Whereas a space average would show little variation with temperature, thermal vibrations should decrease with decreasing temperature and eventually reduce to zero at 0 K. Initial work along these lines was conducted by Williams and Megaw (1964) at -180°C and by Quarani and Taylor (1971) at 300 and 600°C , who used two-dimensional Weissenberg data with intensities measured by multiple film techniques. The results of refinement based on more complete and accurate three-dimensional intensity data are needed to confirm these initial results. Some high-temperature data have been collected by Prewitt *et al.* (1974), but no structural details on low albite are available.

Experimental

In order to collect intensity data at high temperatures, a Pt-resistance microfurnace was constructed to fit the 9-inch diameter χ circle of a Syntex P1 4-circle diffractometer. Calibration against the thermal expansion of quartz and the melting points of $\text{Ba}(\text{NO}_3)_2$, NaCl, and Au was reproducible to within 10°C . However, the temperature at $\chi = 0$ was 14°C higher than at $\chi = 90$ and 180 degrees. In this position the furnace is inverted and convection is im-

paired. Lacking the equipment to compensate for temperature variations as a function of the χ angle, this inaccuracy had to be tolerated.

Tiburon albite (Ab_{99.76} Or_{0.26}) was chosen for these experiments for its purity. A sample of suitable crystallinity, checked by transmission Laue photographs, was ground to a nearly spherical shape of 0.25 mm diameter using a sphere grinder (Bond, 1951). The crystal sphere was mounted in a silica-glass capillary using a cement of ground mullite and a binder ("Zircobond 6" by Zircoa Corp.). The capillary was then evacuated and sealed. Intensities of 1980, 1990, and 2002 reflections were measured at 500, 750, and 970°C respectively, using the ω -2 θ method on the diffractometer, with MoK α radiation monochromatized by reflection from a graphite "single" crystal, and a scintillation counter. A variable scan rate was used, the minimum being 2°/min. Unfortunately, while cooling from 250°C to room temperature, the capillary fractured as a result of thermal stresses. The crystal was lost; thus, post-analysis compositional data and room-temperature refinement are lacking. For the present, Wainwright's room temperature data on Tiburon albite [in Smith (1974)] are being used.

The intensity data were corrected for Lorentz, polarization, and absorption effects. The glass of the capillary and the furnace were of nearly constant thickness (0.02–0.03 mm). Several widely spaced diopside reflections were collected with and without the furnace enclosure. Absorption effects were constant within counting error. Hence the absorption effects due to the glass of the capillary and the furnace enclosure were neglected. Least-squares refinement of the structure was initiated using the RFINE program (Finger, 1969). The atomic scattering fac-

tors of Na, Al, Si, and O were taken from Cromer and Mann (1968). Anomalous dispersion corrections were made according to Cromer and Liberman (1970). The observed structure factors (F_o 's) were weighted by $1/\sigma^2(F_o)$, where $\sigma(F_o)$ is the standard deviation of F_o , as measured by the counting statistics. Four cycles of refinement using isotropic temperature factors resulted in R factors of 0.090, 0.087, and 0.104 for 500, 750, and 970°C respectively. A further five refinement cycles using anisotropic temperature factors were required to achieve convergence. The final R factors are 0.032, 0.035, and 0.039 for the same respective temperatures. Cell dimensions, atomic coordinates, and thermal ellipsoid parameters are listed in Tables 1, 2, and 3 respectively. Table 4² lists the observed and calculated structure factors. Polynomial regression equations to the first and second order have been fitted to all temperature-dependent data, and the coefficients are listed in the appendix. Bond distances and angles are listed in Tables 5 and 6.

Results and discussion

Cell dimensions, strain ellipsoids and atomic parameters as a function of temperature

The cell dimensions were measured at room temperature and 250°C as well as at 500, 750, and 970°C prior to data collection and remeasured upon cooling. No hysteresis effects were observed. The axial dimensions and cell volume all increase with increasing temperature (Fig. 1). However, for monoclinic and triclinic crystals, the cell expansion in terms of the axial dimensions can be misleading, as the princi-

*Data from Wainwright (in Smith, 1974)

graciously computed the strain ellipsoids based on our unit-cell data measured at 25, 500, 750, and 970°C using his program STRAIN. The results, shown in Table 7 and Figure 3, agree quite well with previous studies.

Although the *a* axis shows the largest variation with temperature, the longest axis of the strain ellipsoid clearly indicates a maximum expansion in a direction 40° away from *a* (Table 7). In addition, the shortest axis, lying approximately in the *b-c* plane, indicates a cell contraction in this direction as temperature is raised.

The cell expansion is principally controlled by adjustments of the aluminosilicate framework itself. Na plays a relatively passive role, for reasons to be discussed later. No single parameter adequately explains the orientation of the thermal strain ellipsoid. The response of the structure to changing temperature appears to be controlled by the interaction of at least three factors. First is the greater flexibility of the framework along the *a* crystallographic axis, which is

*Data from Wainwright (in Smith, 1974)
 ATB indicates the O_A-T-O_B angle etc.

the direction of the aluminosilicate "double crankshafts" (Smith, 1974). Two additional factors have a modifying effect on the simple stretching of the crankshafts. There is a tendency for the structure to overcome the collapse about the small Na atom with increasing temperature. Although inhibited by the ordered Si/Al topology, every atom slightly approaches a position of monoclinic geometry (Table 2). This is indicated by a decrease in the obtuse α angle and the approach of β to the ideal sanidine value of 116.0 (or monalbite $\beta = 116.1$; Okamura and Ghose, 1975) (Fig. 2). However, the acute γ angle also decreases, although certainly much less than α and β . This may reflect the modifying effects of Si/Al order. A second restraint on the crankshaft stretching is imposed by the O_{Al} atoms which join adjacent crankshafts in the c direction (Fig. 4). Where one crankshaft opens upward, it is joined along the diago-

nals to an adjacent crankshaft, which opens downward, thus inhibiting one another's freedom of motion. The result appears to be a stretching between the two O_{Al} joins. If so, this action would cause the diagonal $T_2(o)$ atoms to move closer to each other. The direction between these two atoms is also the direction of the negative axis of the thermal expansion ellipsoid.

It should be noted at this point that the sample being analyzed at elevated temperatures remains a nearly completely ordered albite with respect to Si/Al, and is therefore not the equilibrium form at the temperatures of analysis. Increasing Si/Al disorder as temperature is raised will certainly contribute to the structural response of the crystal.

Na anisotropy as a function of temperature

As regards the principal problem, that of the Na anisotropy, the isotropic equivalent temperature factor is plotted against temperature in degrees Kelvin in Figure 5. Included are the room-temperature data of

Fig. 1. Cell dimensions and volume of Tiburon albite vs. temperature. Error bars represent \pm one standard deviation. The curve is fitted to the values measured with increasing temperature. Where the cell dimension measured as temperature was decreased differs from these values by greater than two standard deviations, it is plotted as a separate symbol.

Fig. 2. Cell angles of Tiburon low albite vs. temperature. Error bars represent \pm one standard deviation.

Wainwright and the 93 K data of Williams and Megaw (1964) as re-refined by Quareni and Taylor (1971). A reasonably good linear fit is demonstrated and extrapolates to $B = 0$ K within error limits. This confirms the hypothesis of Quareni and Taylor (1971) that the Na anisotropy is strictly the result of thermal vibration about a single point. If there were some spatial disorder, B at 0 K would have a magnitude sufficient to encompass the multiple positions. This is

Fig. 3. Stereographic projection of the minimum (x), intermediate (y), and maximum (z) axes of the thermal expansion ellipsoids for Tiburon low albite at 25 \rightarrow 500°C, 25 \rightarrow 750°C, and 25 \rightarrow 970°C respectively in the direction of the arrows. Cell axes are included.

readily demonstrated by the data points for high albite obtained thus far, by Williams and Megaw (1964) at 93 K (hydrothermal synthesis at 700°C), by us at 298, 773, 1023, and 1253 K (Tiburon albite, heat-treated at 1080°C for 60 days), and by Prewitt *et al.* (1976) at 297, 573, 873, 1023, 1173, 1363 and 1378 K on a synthetic high albite (annealed at 1060°C for 40 days). A linear fit to the data extrapolates to a B value of 5.85\AA^2 at 0 K. This large B value, at a temperature where thermal motion should be zero, can only be explained by some multiple position effect, a result also obtained by Prewitt *et al.* (1976).

As a check of the results for low albite, R_3 , the longest axis of the thermal ellipsoid, was plotted against temperature in degrees Kelvin. If the anisotropy is a result of thermal vibrations, it should also reduce to zero at 0 K. If $(R_3)^2$ is plotted against

Table 7. Tiburon low albite: principal strain components of thermal expansion

Temperature Range, °C	Principal Strain Components per 1°C $\times 10^{-5}$	Orientation of Principal Axes		
		Angle (degrees) with respect to:		
		+a	+b	+c

	-0.47(3)	104(1)	133(1)	40(1)

temperature (Fig. 6), the curve becomes much more linear, like the one for *B*, and also extrapolates to $(R_3)^2 = 0$ at 0 K. As in the case for *B*, the units become Å^2 vs. temperature. The linearity of this relationship is in accordance with the Debye model for thermal motion, which predicts a direct proportionality between temperature and the square of the mean square amplitude of vibration. There is a slight, but consistent, deviation from linearity at higher temperatures, which may be due to changes in the relative strengths of Na–O and T–O bonds or, more likely, restrictions imposed on the Na vibrations by the aluminosilicate cage.

Figure 7 shows the coordination of the Na atom in low albite at 970°C. The thermal displacement ellipsoids of Na and O are included. The R_3 axis for Na is nearly parallel to the *b* crystallographic axis and normal to the Na–O_{A2} bond, the shortest of the Na–O bonds. This direction permits the maximum movement of the Na atom without obstruction by the neighboring atoms. The high anisotropy of the Na atom in a cage which can accommodate the much larger K atom seems quite reasonable in this light. A subservient role of Na with respect to cell expansion is indicated.

Isotropic temperature factors, Na–O and T–O bond lengths and angles as a function of temperature

Equivalent isotropic temperature factors for Si, Al, and O are also plotted against temperature (Fig. 8) and likewise show linear fits extrapolating to $B = 0$ at 0 K. The average oxygen *B* value actually extrapolates to $B = 0.1 \text{ Å}^2$ at 0 K, but this is within the error limits of a zero value. If this magnitude is real, it may result from unequal Si–O and Al–O bond lengths combined with incomplete Si/Al order.

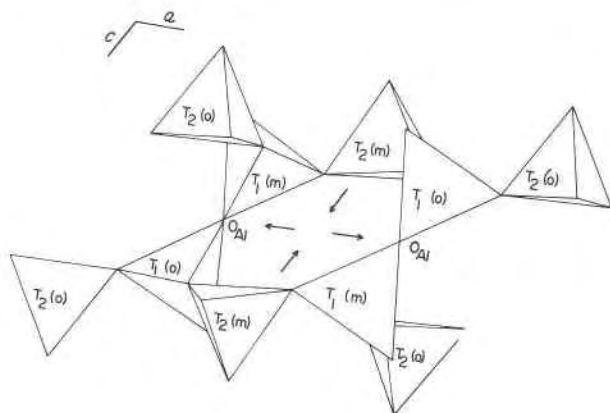

Fig. 4. Adjacent tetrahedral crankshaft chains joined by O_{A1} links. Arrows indicate stretching direction between the O_{A1} links and the resulting approach of the diagonal T₂(*m*) atoms.

Fig. 5. Isotropic equivalent temperature factor (*B*) for the Na atom in high and low albite vs. temperature. Dots represent low albite, triangles represent our data on high albite, and squares represent the data of Prewitt *et al.* (1976) on high albite.

The bond angles as a function of temperature display a quite linear fit, indicating a smooth, continuous change over the observed temperature range. Rarely does an O–T–O angle change by more than half a degree over the observed temperature range, while changes of three or more degrees are quite common for T–O–T angles. Thus it is clear that the angles between adjacent tetrahedra are more flexible and respond more readily to lattice strain than do angles within a tetrahedron.

Most of the Na–O bond lengths, plotted as a function of temperature (Fig. 9), show a substantial increase as temperature is raised. The two longest bonds, however, become shorter with increasing temperature. This apparently results from a straightening of the aluminosilicate cage, which may be thought of as collapsed about the small Na atom, especially at low temperatures. Note that there is no consistent correlation between the size of a Na–O bond length and the magnitude of the change in that bond length with temperature. If one expected the Na atom to participate in the thermal response of the structure in a dominant fashion, the shorter Na–O bond lengths ought to increase more readily than the longer ones, which is not the case.

In contrast to the expansion of Na–O bonds, the T–O bonds remain nearly constant or decrease slightly with increasing temperature. This behavior is

Fig. 6. Tiburon low albite. Long axis of the Na thermal ellipsoid (R_3) squared vs. temperature.

Fig. 7. Na atom coordination and thermal ellipsoid in Tiburon low albite at 970°C.

unexpected, since the predominant cell response of this framework silicate is expansion. Similar apparent contractions of Si-O bonds with increasing temperature have been observed in other silicate minerals (Smyth and Burnham, 1972; Smyth, 1973, 1974; Ohashi, 1973; Sueno *et al.*, 1973 a, b; Ohashi and Finger, 1975; Finger and Ohashi, 1976; Hazen, 1976), which have been attributed to: (1) the strength of the

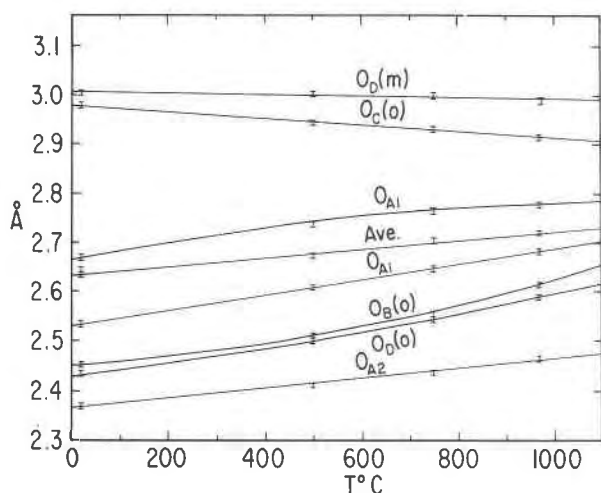

Fig. 8. Isotropic equivalent temperature factors for Al, Si (average), and O (average) for low Tiburon albite *vs.* temperature.

Si-O bond, (2) complex M-O-Si interactions, and (3) thermal vibration effects.

Although the Si-O and Al-O bonds are indeed stronger than Na-O bonds, for these bonds to remain constant requires a symmetrical potential energy well. For them to actually decrease, the outer wall must be steeper than the inner one. Although there are no direct theoretical constraints, the possibility of the electronic interaction matching or surpassing that of the coulomb nuclear repulsions as a function of the

atomic separations is prohibitively remote. This behavior has never been observed in nature for any diatomic molecule, including Si-O and Al-O (see Herzberg, 1950).

The possibility may yet exist that a shared bond may transfer energy to a T-O bond at elevated temperatures and thereby decrease the bond length. Thus

Fig. 10. An example of the temperature corrections of Busing and Levy (1964) applied to a typical T-O bond length in Tiburon low albite as a function of temperature. The uncorrected values with ± one standard deviation are included for reference.

the greatly lengthened Na-O bonds might shift energy to the T-O bonds via the common oxygen. Such interactions have been proposed for Mg-O-Si interactions in olivine (Hazen, 1976). As most interactions are T-O-T, and M-O bonds are fewer in feldspars than in olivine, the nature of the M-O-Si interaction should be clearer. If this interaction is responsible for the observed T-O behavior, the magnitude of the change in T-O bond length should show a strong correlation with the magnitude of the change in the neighboring Na-O bond length. Table 5 and the regression equations in the appendix indicate no such correlation. Nor, for that matter, is there a correlation between the magnitude of the T-O bond length change and the size of the neighboring Na-O bond

*There is no room temperature data available with temperature corrections. Therefore the curves for the corrected bondlengths are fitted to only 3 data points while the room T curves are for 4.

length itself. Data on the structure of quartz (Young, 1962) also show an apparently constant or slightly decreasing Si-O bond length as temperature is raised, with no octahedral atoms in the structure to donate bond strength.

We believe that the apparent contraction of many T-O bonds in silicates probably results from errors in measurement caused by thermal motion. The refinement method used for X-ray data produces as atomic positions the centers of ellipsoids fitted to the average electron-density distribution for that atom. As pointed out by Busing and Levy (1964), the calculated distance between two such static positions may differ from the time-averaged mean separation of the true vibrating atom centers.

The bond lengths, corrected using the four modeled interactions (after Busing and Levy, 1964), are listed in Table 8. To illustrate the magnitude of these corrections to the present study, Figure 10 shows how the various corrections affect the computed length of a single T-O bond, in this case T₁(o)-O_{A1}, over the temperature range studied. Note that the T-O distance increases with increasing temperature for most corrected curves. This is indeed true for all T-O bonds.

Until data on the distribution of individual atom pairs during vibration becomes available, we cannot

accurately determine the actual bond length within the range of the upper and lower limits. Thus these limits effectively become the error limits of the bond-length estimation. At high temperature this error can be more than 50 times the standard deviation error due to measurement. At 970°C this range is generally about 6 percent of the uncorrected bond length. In addition, bond-angle calculations involve uncertainties in the joint distribution of three atoms. It is thus virtually impossible to correct bond angles with any accuracy when large thermal motions are involved. Hopefully infrared and Raman spectroscopic techniques at elevated temperatures will supply much-needed data concerning the nature of these vibrations.

Summary and conclusions

1. The thermal strain ellipsoids of low albite indicate cell expansions in directions significantly different from the axial directions. The minimum expansion direction actually amounts to a contraction of the cell in certain directions as temperature is raised. No single structural parameter adequately explains the cell-expansion behavior. Presumably three factors contribute to the observed responses: (1) the greater flexibility of the framework along the "double crankshaft" chains, (2) restrictions imposed on the afore-

mentioned flexibility by the linking of adjacent crankshafts along the *c* direction, and (3) a small, but progressive approach toward monoclinic geometry.

2. The marked anisotropy associated with the Na position in low albite results solely from highly anisotropic thermal vibration about a single node as suggested by Quareni and Taylor (1971). Results on high albite indicate some form of positional disorder as well.

3. When dealing with bond lengths and angles in crystalline solids at elevated temperatures, corrections for the effects of thermal motion must be considered. As it is presently impossible to describe completely the true mutual distribution of all the atom centers as they vibrate, rather large uncertainties may result. In this study these corrections are sufficient to reverse the apparent trend toward decreasing *T*-O bond lengths with increasing temperature in most of the uncorrected observations.

Acknowledgments

We thank those people who contributed time, equipment, or technical advice to this study: Dr. B. W. Evans, for his sample of Tiburon albite; Mr. James Carter; Mr. M. Burton, Mr. Val Kiefer, Dr. James Blacic, and Dr. Stewart McCallum, for technical assistance. Dr. L. W. Finger, Geophysical Laboratory, Washington, D. C. kindly calculated the thermal strain ellipsoids. Drs. R. M. Hazen and L. W. Finger critically read the manuscript and offered suggestions for improvement.
