Abstract

X-ray diffraction data collected on a single-crystal specimen of CuS₂ show that despite its optical anisotropy CuS₂ apparently has the cubic pyrite structure, with \( a = 5.7891(6) \) Å. Precession and Weissenberg photographs fail to reveal any reflections which violate the requirements for space group \( Pa\bar{3} \). Such reflections, however, were observed in four-circle diffractometer measurements, but they are shown to result from multiple diffraction effects. Refinement of the structure in space group \( Pa\bar{3} \) using 209 intensity data gives a weighted residual of 0.014 and \( x(S) = 0.39878(5) \). A comparison of the refined structure with other pyrite structures suggests that copper in CuS₂ has a formal valence of 2+ and three antibonding electrons. Also, the CuS₆ octahedron is only slightly distorted, which is in contrast with the square-planar coordination usually found for Cu²⁺.

Introduction

Disulfides of the transition elements Mn through Zn crystallize in the pyrite structure. The Mn, Fe, Co, and Ni members of this group occur as minerals, and their structures have been refined. CuS₂ and ZnS₂ are not found in nature, but they have been synthesized at high temperatures and pressures. This paper reports the results obtained in a study of the crystal structure and optical properties of CuS₂.

CuS₂ is of interest for two reasons. First, its crystal chemistry is unique. Nakai et al. (1978) have shown through X-ray photoelectron spectroscopy that most copper sulfides contain only Cu⁺; however, our crystal-chemical evidence indicates that copper in CuS₂ is divalent. The copper is coordinated by six sulfur atoms in a trigonal antiprism slightly distorted from an octahedron, rather than in its usual square-planar coordination. Second, optical evidence for non-cubic symmetry has been reported (Taylor and Kullerud, 1972), but not explained in terms of the crystal structure. Similar, but less intense, optical effects have been reported for FeS₂ (Stanton, 1975; Gibbons, 1967). These authors disagree as to whether the anisotropy is entirely a surface feature or intrinsic to the crystal structure. There is also disagreement with respect to the X-ray diffraction studies on FeS₂. Finklea et al. (1976) found no deviations from cubic symmetry, but Bayliss (1977) concluded that at least some pyrite crystals are triclinic. Because optical anisotropy has always been observed for CuS₂, we decided to investigate its crystal structure to provide further information on this intriguing problem.

Experimental

The CuS₂ crystal used is a small (0.13 × 0.12 × 0.08 mm) rectangular prism selected from material reported by Bither et al. (1968). Although polished sections of these crystals are anisotropic in reflected light, long-exposure precession and Weissenberg photographs failed to reveal any diffraction spots which are inconsistent with the requirements for space group \( Pa\bar{3} \). This crystal was mounted on a Picker four-circle diffractometer and its lattice parameters were determined from twelve automatically-centered reflections using MoKα radiation. The least-squares refinement of the orientation matrix (Tichý, 1970) provides an unconstrained estimate of all unit-cell lengths and angles; with the precision obtained, the geometry of the cell is cubic with \( a = 5.7891(6) \) Å. This value agrees well with previous determinations using X-ray powder diffraction techniques: \( a = 5.7898 \) Å (Bither et al., 1968) and \( a = 5.7897 \) Å (Taylor and Kullerud, 1972).
we observed, as Bayliss had for FeS₂, several forbidden reflections (an example for 500 is shown in Fig. 1a). However, all the forbidden reflections we observed could be eliminated by rotating the crystal around the diffraction vector to some arbitrary $\Psi$ angle (Fig. 1b). $\Psi$ is a right-handed rotation whose zero is defined when $\omega = 0$ with an $(hkl)$ plane in diffracting position. Further information was provided by making integrated intensity measurements at every $0.5^\circ$ in $\Psi$ from $-90$ to $+90^\circ$ and plotting the results as $I_{\text{obs}}/2\sigma_i$ vs. $\Psi$ (Fig. 2). This figure shows that, even though the diffracted intensity is above the detection limit ($I_{\text{obs}}/2\sigma_i = 1$ in this figure) at some $\Psi$ values, it is below that limit at many other $\Psi$ values. Because a Bragg reflection’s intensity should not become undetectable at any $\Psi$ value, we conclude that all such observed reflections, forbidden for space group $Pa\bar{3}$, are the result of multiple diffraction effects. We also believe that, although Bayliss (1977) may have been working with non-cubic FeS₂ crystals, he did not give sufficient information to eliminate the possibility that the extra reflections he observed were caused by multiple diffraction.

Coppens (1968) discussed criteria for the occurrence of multiple Bragg scattering, and concluded that reciprocal lattice points within 0.003Å⁻¹ of the Ewald sphere could satisfy the requirements for multiple diffraction. In order to test the applicability of this idea to FeS₂ and CuS₂, we calculated the number of reciprocal lattice points which meet this criterion for various sets of diffraction conditions. For the 100

Fig. 1. $\theta$–$2\theta$ scans for 400, 500 and 600 at two positions around the diffraction vector: $\Psi = 0^\circ$ (1a) and $\Psi = 151^\circ$ (1b). $\Psi$ is a right-handed rotation whose zero is defined when $\omega = 0$ with an $(hkl)$ plane in diffracting position.

Fig. 2. Results of integrated intensity measurements at every $0.5^\circ$ around the diffraction vector from $-90$ to $90^\circ$. The intensity is normalized to the detection limit ($2\sigma_i$); thus, a value $>1$ is considered to be observed.
and 300 reflections of CuS₂ (MoKα radiation), there are many reflections within 0.003Å of the Ewald sphere in any orientation tried thus far. When b* is initially parallel to the X-ray beam and c* is normal to the equatorial plane, there are 47 other reciprocal lattice points near the sphere when 100 is in diffracting position. Similar results are obtained for FeS₂. Therefore, it would be extremely difficult, using four-circle geometry, to prove that the extra reflections are a result of causes other than multiple diffraction.

Diffraction intensities for structure refinement were measured on a Picker four-circle diffractometer at the Geophysical Laboratory (Washington, D.C.), using Nb-filtered MoKα radiation with the diffractometer operating in the θ–2θ scan mode. 253 reflections were measured representing all h, k, l > 0 and 0° < 2θ < 60°, except for certain h00 which were inadvertently omitted. Scan rates and background counting times were adjusted for each reflection (Finger et al., 1973) to produce a value of 0.01 for σI / I. Reference reflections showed no significant variations during the course of the data collection. Intensities were corrected for Lorentz and polarization effects as well as absorption. The absorption correction was computed using a modified version of Burnham’s (1966) program with the mass absorption coefficients of Cromer and Liberman (1970). This program also calculates a geometric factor (Zachariasen, 1967) used in the extinction correction.

Refinement

The program RFINE4 (Finger and Prince, 1975) was used for full-matrix least-squares refinement. Neutral scattering factors of Cromer and Mann (1968) along with anomalous dispersion coefficients of Cromer and Liberman (1970) were used. Equivalent reflections were not averaged to allow for refinement of anisotropic extinction. Only reflections with I > 2σI were used in the refinement.

The structure was refined in space group Pa3 using starting parameters from previous unpublished refinements. In the pyrite structure, the metal atom is at the origin and the nonmetal one at x, x, x; thus, there is one variable positional parameter. The starting model was one having isotropic temperature factors and no correction for secondary extinction. Subsequent models included anisotropic thermal motion and both isotropic (Zachariasen, 1967) and anisotropic (Coppens and Hamilton, 1970; Thornley and Nelmes, 1974) secondary extinction corrections. The final model contained corrections for anisotropic thermal motion and anisotropic type 2 extinction. These refinement results are shown in Table 1, and the observed and calculated structure factors are available.²

Table 2 gives the final positional parameters, anisotropic temperature factor coefficients, equivalent isotropic temperature factors (Hamilton, 1965), and rms displacements along the unique directions calculated from the anisotropic temperature factor corrections.

Secondary extinction

The secondary extinction model used to correct these data is a modification of the Zachariasen (1967) model by Coppens and Hamilton (1970). The anisotropic correction is significant at the 99.9 percent level (Hamilton, 1965) over the isotropic one (wtd. $r = 0.017$). The extinction correction is given by (Zachariasen’s equation 1)

$$P = P_0 y$$

where $P$ is the integrated intensity, $P_0$ the kinematical approximation and $y$ the extinction factor. In RFINET 4,

$$y = [1 + \beta(\theta) F_0^2 r^*]^{-1/2}$$

where $\beta(\theta)$ is a geometric factor, calculated for each reflection during the absorption correction, and $r^*$ is a refiinable parameter. For the type 2 anisotropic extinction model, $r^*$ is replaced with

$$r^* = (N^T W N)^{-1/2}$$

$N$ is a unit vector and $W$ a second-rank tensor whose components are varied during the refinement. According to the model, this tensor represents an ellipsoidal-shaped, ideal-crystal domain. The $W_{ij}$ components and the resulting ellipsoid's principal axes lengths and orientations for CuS$_2$ are given in Table 3. Although this extinction model seems to adequately correct for the effects in our data, recent discussions of extinction (Becker, 1977; Lawrence, 1977) make us doubt that a physical interpretation of the ellipsoid in Table 3 is justified.

Because $\beta(\theta)$ is always positive, equations 1 and 2 show that $r^* > 0$, yet Bayliss (1977) obtained $r^* = -0.156 \times 10^{-4}$ from his refinement of FeS$_2$. The extinction parameter is correlated with the temperature factors by interaction with the scale factor. The sense of this effect reduces the temperature factors as $r^*$ is decreased and could have led to the non-positive temperature factors of Bayliss.

Thermal ellipsoids

The thermal ellipsoids of both the metal and nonmetal atoms in the pyrite structure are constrained to be uniaxial with their unique axes along the cube diagonal. The rms thermal amplitudes in this direction and in the plane normal to it for copper and sulfur are listed in Table 2. The thermal ellipsoid for copper is only slightly anisotropic. The ratio of the largest to the smallest rms displacement is 1.06. Its largest displacement is along the trigonal compression axis of the octahedron. Sulfur’s thermal ellipsoid is more an-

isotropic. The ratio of its displacements is 1.24, with the largest displacement normal to the disulfide bond. Apparently, the short sulfur–sulfur distance limits motion along this bond.

Structure

Figure 3 shows the two types of coordination polyhedra in CuS₂. Copper is surrounded by six sulfur atoms in a trigonally-distorted octahedron, and sulfur is coordinated by three copper atoms and one other sulfur atom in a distorted tetrahedron. The CuS₂ octahedra are linked by corner sharing. The sulfur–sulfur distance in pyrite structures approaches that in sulfur itself, and the sulfurs are considered to be bonded to each other.

Some important interatomic distances and angles for the first-row transition-element pyrites are listed in Table 4 and shown in Figure 4. These values show that the parameters for CuS₂ lie along the trends established by the naturally-occurring pyrite structures, and suggest that copper has the same oxidation state (2⁺) as the other metals in this group. This also suggests that the discussions of bonding in these materials (Bither et al., 1968; Brostigen and Kjekshus, 1970; Goodenough, 1972) are applicable to CuS₂. These models attribute the increase in the metal–sulfur bond length (Fig. 4) to an increase in the number of antibonding electrons. Three are assigned to the copper in CuS₂. In addition, Kjekshus and Nicholson (1971) suggest that these electrons produce a redistribution of electron density which causes the decrease in the sulfur–sulfur bond length (Fig. 4).

Usually, Cu²⁺ is found in square-planar coordination. If the bonding is sufficiently ionic, this can be ascribed to Jahn–Teller distortion. However, Jahn–Teller distortion is unusual in transition-metal sul-

Fig. 4. Bond-length variation for first-row transition-element disulfide pyrite structures including the CuS₂ results.
this series and that the distortion decreases through CuS₂.

Non-cubic symmetry

The optical anisotropy observed for CuS₂ and FeS₂ has raised questions about the correct symmetry for these structures. If this anisotropy were a function of the deviation from cubic symmetry, CuS₂ should not be cubic. The anisotropy is ubiquitous for CuS, and the deviation from cubic symmetry, CuS, should not be important for these structures. If this anisotropy were a function of variables and a low residual, it is difficult to obtain a statistically significant improvement in the refinement through decreasing the symmetry (increasing the number of variables). For example, one lower-symmetry model suggested by optical data (Gibbons, 1967) is a trigonal structure with its c axis along one of the cube diagonals in the pyrite unit cell. We refined the CuS₂ data in the R3 space group with the c axis along [111] of pyrite. That model has 23 variable parameters and gives a residual of 0.016. A residual of 0.013 would be necessary for a significant improvement (95 percent confidence level; Hamilton, 1965) over the cubic model.

These arguments suggest that the optical anisotropy is a surface effect. When we examined polished sections of our material, we observed an increase in the intensity of these optical effects with time. After a month’s exposure to air, the intensity of these optical effects with air for variable lengths of time, and examined with a scanning electron microscope. The results to date are inconclusive. A second phase was observed on some samples, but we have not been able to obtain repeatable results.

Conclusions

Although polished sections of CuS₂ are optically anisotropic, no structural evidence has been found for symmetry lower than cubic. A similar anisotropy in FeS₂ may indicate that some of these crystals are not cubic. However, we believe the refinement by Bayliss does not adequately test this possibility. Trends established by naturally-occurring pyrites suggest that copper in CuS₂ behaves similarly to the metals in other pyrites: it has a 2+ formal valence and three antibonding electrons. The refined structure shows that the CuS octahedron is only slightly distorted, which probably indicates crystal field distortions are not important for these materials.

Acknowledgments

We thank Larry W. Finger for collecting some of the X-ray data used in this study and for discussions concerning secondary extinction effects. We also thank Robin Reichlin who performed the scanning electron microscope experiments. This research was supported by NSF grant EAR 77-13042.
