14

15 **ABSTRACT**

16 Chemical Vapor Transport (CVT) Reaction is an important and efficient method of

17 synthesizing pyrite crystals. CVT-grown pyrites have been comprehensively investigated

18 for physical properties and elemental chemical compositions. However, the isotopic

19 compositions have not been paid attention. In this study, four series of pyrite crystals

20 (PY3, PY4, PY5, PY6) were synthesized using CVT method, with PY5 undoped and the

21 others doped with nickel. The synthesized crystals were characterized qualitatively with

22 confocal laser Raman microspectroscopy and quantitatively by EMPA, LA-ICPMS,

23 SIMS, and IRMS. The synthetic products are irregular polycrystalline aggregates or cubic

24 and octahedral monocrystals, with characteristic Raman bands at ~344 cm^{-1}, ~380

25 cm^{-1}/377 cm^{-1}, ~427 cm^{-1}/430 cm^{-1}, and S/Fe weight and atomic ratios of 1.15–1.17 and

26 2.01–2.04 respectively indicative of pyrite. The pyrites contain traces of inevitable

27 impurities such as Si and Br. The nickel contents of Ni-doped pyrites are heterogeneous,

28 39–27300 ppm for PY3, 24–21700 ppm for PY4, and 57–2610 ppm for PY6. By

29 comparison, the δ^{34}S values obtained by SIMS are relatively homogeneous (PY3 = 17.3 ±

30 0.9‰, PY4 = 17.7 ± 0.8‰, PY5 = 17.9 ± 0.8‰, PY6 = 17.7 ± 0.6‰, ±2SD), and are

31 consistent with IRMS δ^{34}S values (17.8 ± 0.2‰ for PY3, 18.3 ± 0.9‰ for PY4, 18.2 ± 0.3‰

32 for PY5, 18.1 ± 0.1‰ for PY6, ±2SD). The homogeneity of ^{34}S/^{32}S suggests that CVT has

33 the potential to synthesize reference materials for the determination of sulfur isotopic

34 composition of pyrite using in-situ techniques. Additionally, we also investigated the

35 matrix effects of nickel in pyrite on the measurement of ^{34}S/^{32}S by SIMS, and a preliminary

36 equation of Δ^{34}S (‰) $= -0.59 \times$ Ni(wt%)$^{0.27}$ was derived for calibration.

INTRODUCTION

Natural pyrite (FeS$_2$) is extremely abundant on the Earth. They are widespread in sediments, (meta-)sedimentary rocks and hydrothermal deposits (Rickard, 2012). However, due to the common occurrences of impurities (e.g., Ni, As, Co, Se, etc.), they cannot be used for certain purposes, for instance, semiconductor with a special requirement of electrical properties. In such cases, pure pyrite or pyrite doped with a specific element needs to be synthesized in the laboratory. Pyrite crystals can be synthesized in high-temperature solid-state (Clark, 1960; Fiechter et al., 1986) or wet-chemical (Xian et al., 2016 and references therein) ways. Chemical Vapor Transport (CVT) Reaction is a solid-state method that has been long and widely applied to synthesizing undoped or specific element-doped pyrite with the use of halogen compound(s) such as AlCl$_3$, KCl, AlBr$_3$, FeBr$_3$ as transport agents (Lehner et al., 2006; Diener and Köppe, 2012; Lehner et al., 2012). CVT-grown pyrite is well crystallized and the monocrystals can be up to millimeters in size. In addition, the crystals are pure FeS$_2$ without other iron sulfide phases.

The optical, electronic, and electrical properties (e.g., resistivity/resistance, carrier concentration, Hall coefficient, Hall mobility) of CVT-synthesized pyrite crystals have been investigated comprehensively for the purposes of, for instance, revealing the causes of low open-circuit voltages (Voigt et al., 2020), confirming the surface conduction (Walter et al., 2017), exploring the effects of dopants (Lehner et al., 2006; Lehner et al., 2012). In comparison, their chemical compositions have not been paid much attention, with the exception of the concentrations of (unintentional) doped impurities, which have been measured using Secondary Ion Mass Spectrometry (SIMS), Electron Probe Micro-analyzer (EPMA), Laser Ablation-Inductively Coupled Plasma Mass Spectrometry (LA-ICPMS), Rutherford Backscattering, ICPMS, Inductively Coupled Plasma Atomic Emission Spectrometry (ICPAES), and Proton Induced X-ray Emission (PIXE) to establish the relationship between impurities and electrical properties (Lehner et al., 2006; Lehner et al., 2012). The isotopic compositions, nevertheless, have not been examined yet.

Reference materials are critical for in-situ analytical methodology such as SIMS and LA-ICPMS. Current reference materials for the in-situ determination of pyrite sulfur isotopic composition are all of natural origin, e.g., Ruttan pyrite, Balmat pyrite (Crowe and Vaughan, 1996; Ireland et al., 2014), Sierra pyrite (LaFlamme et al., 2016), Sonora

77   pyrite (Farquhar et al., 2013; Chen et al., 2015), Maine pyrite (Philippot et al., 2007;
78   Muller et al., 2017; Philippot et al., 2018), PPP-1 pyrite (Li et al., 2017; Li et al., 2018; Li
79   et al., 2021), and Py-1 pyrite (Li et al., 2021). The main problem with natural reference
80   materials is the limited quantity. With the rapid increase in the application of in-situ
81   analysis, accelerated consumption of the reference materials can be expected. As a
82   consequence, seeking and developing new reference materials will be needed. Recently,
83   some pioneering work (e.g., Feng et al., 2022) has been conducted to artificially
84   synthesize sulfide reference materials in the laboratory for LA-MC-ICP-MS analysis
85   using high-temperature melting and plasma-activated sintering, which provides an
86   alternative way to develop reference materials for in-situ analysis. CVT-grown pyrite
87   crystals, with their moderate to large sizes, have the potential to act as reference materials,
88   provided that the composition is homogeneous.

89   This study synthesized undoped and nickel-doped pyrite crystals via CVT reactions.
90   We measured the $^{34}S/^{32}S$ of these crystals in situ using SIMS (SHRIMP-SI) and the
91   concentration of nickel in situ using EPMA and LA-ICPMS to examine the distribution
92   of sulfur isotopes and doped trace element. By these investigations, we aim to assess
93   whether CVT-synthesized pyrite crystals have the potential to be used as reference
94   materials.

95

96   **METHODS**

97

98   **Experimental**

99

100   The pyrites were synthesized using Chemical Vapor Transport (CVT) Reaction
101   method described in Lehner et al. (2006). Four series of pyrite crystals were synthesized
102   (PY3, PY4, PY5, and PY6) from four experiments at the Guangzhou Institute of
103   Geochemistry, Chinese Academy of Sciences (GIGCAS).
104   For the synthesis of PY4, PY5, and PY6, purchased FeS (99.9%, Macklin) was well
105   mixed with sulfur (99.999%, damas-beta) and nickel (99.9%, Macklin) powder in a clean
106   mortar, with a $(FeS/S)_{molar}$ ratio of approximately 5/4 following Lehner et al. (2006). A
107   small amount of $FeBr_3$ powder (99%, Adamas) was rapidly loaded into a clean silica
108   glass tube (6-mm ID, 10-mm OD; cleaned using ethanol, HCl, and deionized water; dried
109   in an oven at 110 °C), and the FeS-S-Ni mixture was then loaded onto $FeBr_3$. The glass
110   tube was subsequently evacuated, and sealed using a torch, resulting in a length of 12 cm
111   (in adjustment to the temperature gradient of the horizontal furnace). The tube was placed
112   in a rapid-quench pressure vessel, which was heated in a horizontal furnace for 14 to 15
113   days with a temperature of ~650 °C at the hot end and ~550 °C at the cold end (a gradient
114   of ~100 °C); the pressure was around 3–11 MPa (Argon gas as pressure medium). The
115   temperature was monitored using a K-type thermocouple. After the experiments, the tube

116   was quenched within several seconds by pulling out and tilting the pressure vessel.

117   For the synthesis of PY3, FeS was synthesized in the laboratory with starting
118   materials of iron (99.9%, Macklin) and sulfur (99.999%, damas-beta). An equimolar
119   mixture of iron and sulfur was loaded into a clean silica glass tube. A silica glass rod (3
120   mm in diameter, 4 cm in length, cleaned and dried) was loaded onto the mixture. The
121   glass tube was then evacuated and sealed, and subsequently was heated to 600 °C and
122   held for 14 days, with a low pressure of around 3 MPa (Argon gas as pressure medium).
123

Analytical_confocal laser Raman microspectroscopy

125

126   The Raman spectroscopic analysis was conducted at GIGCAS. The analyses were
127   performed on recovered crystals. The Raman spectra were obtained using a
128   high-resolution confocal Raman microscope WITec alpha300 R system equipped with a
129   frequency doubled Nd:YAG laser emitting at 532 nm (fiber-coupled). A Zeiss 50 ×
130   objective was used to focus the laser onto an approximately 1-μm spot. A diffraction
131   grating of 300 g/mm was used to disperse the light. The spectrometer was equipped with
132   a back-illuminated CCD camera. Single spectrum acquisition mode was used. The
133   surface laser power was 6–10 mW. A pure silicon wafer (111) (520 cm^{-1}) was used to
134   calibrate the spectra before the analysis of experimental products. The scan range was
135   100–4000 cm^{-1}. In order to optimize the spectra and obtain sufficient signal-to-noise ratio
136   to characterize the solid phases, 10 accumulations of 1-second integration were
137   conducted. The obtained raw Raman spectra were processed with cosmic ray removal and
138   background subtraction.
139

Analytical_electron microscopy

141

142   The synthesized crystals were selected under a binocular microscope and cast in
143   25-mm epoxy mounts together with Ruttan pyrite and Balmat pyrite (reference materials
144   for SIMS analyses), and were then ground and polished to expose the mid-planes of most
145   grains.

146   Back-scattered electron (BSE) imaging was conducted using a JEOL JSM6610A
147   Analytical SEM (Scanning Electron Microscope) at the Research School of Earth
148   Sciences (RSES), The Australian National University (ANU). The instrument was
149   operated at 15 kV with images obtained at a loading current of ca. 50 μA with working
150   distance of 10 mm.

151   Chemical compositions of these synthesized crystals were measured using a JEOL
152   8530F Plus electron probe micro-analyzer (EPMA) equipped with five
153   wavelength-dispersive spectrometers and a Schottky Field Emission (FE) gun at the
154   Centre for Advanced Microscopy (CAM), ANU. The analytical conditions were 15 kV

155 (acceleration voltage), 30 nA (beam current), and 20 μm (spot size). Counting times were
156 10 seconds (peak and background) for major elements and 50 or 60 seconds for trace
157 elements. Calibrations were made using synthetic and natural ASTIMEX mineral and
158 metal standards: Si (sanidine) (*Crystal: TAP*), Br (TlBrI) (*Crystal:* TAPL), S (pyrite), Cl
159 (Tugtupite) (*Crystal:* PETL), Fe (pyrite), Ni (pentlandite) (*Crystal:* LIFL). Limits of
160 detection were typically 20 to 150 ppm. Data were processed using full ZAF corrections.

161

162 **Analytical_laser ablation ICP-MS**

163

164   Trace element abundances were determined using a 193 nm wavelength excimer
165 laser (110 ArF Coherent COMPexPro, Lambda Physik) based "HelEx" ablation system
166 equipped with an Agilent Technologies 7700 quadrupole inductively coupled plasma
167 mass spectrometer (ICP-MS) (Eggins et al., 2005) at RSES, ANU. The sampling cell was
168 a "HelEx" two-volume vortex cell in an atmosphere of Ar and He. The laser spot size was
169 28 μm in diameter. Data acquisition involved a 20-second background measurement
170 followed by 45 seconds of ablation, with a repetition rate of 5 Hz and laser energy of 80
171 mJ. Dwell times on each isotope are 0.01 to 0.05 second, totaling about 0.28 second for
172 each mass sweep. In addition to the doped element nickel, other trace elements were also
173 measured; silicon was analyzed to detect whether there are contaminations by the silica
174 glass tube, bromine was measured to investigate whether or not there is bromine
175 involvement in the products via the transport agent $FeBr_3$. The following masses were
176 measured: ^{29}Si, ^{34}S, ^{35}Cl, ^{49}Ti, ^{53}Cr, ^{57}Fe, ^{59}Co, ^{60}Ni, ^{77}Se, and ^{79}Br. Data were reduced
177 and signals were integrated offline using the software package Iolite (e.g., Hellstrom et al.,
178 2008; Paton et al., 2010, 2011). The results were calibrated against MASS1 with Fe
179 determined by EPMA as the internal standard. Other reference materials including NIST
180 SRM 610, 612 and BCR2G synthetic glasses (Jochum et al., 2005, 2011; Marks et al.,
181 2016 and references therein), BB1, BB2 and SY scapolites (Kendrick, 2012), STDGL3
182 (Steadman et al., 2020), Ruttan and Balmat pyrites were also measured as monitors for
183 data quality control.

184

185 **Analytical_SIMS**

186

187   Sulfur isotopic compositions ($^{34}S/^{32}S$) of the synthesized crystals were measured on
188 SHRIMP-SI (Sensitive High Resolution Ion Microprobe - Stable Isotope) at RSES, ANU.
189 The mounts were thoroughly cleaned and dried before being gold-coated and loaded onto
190 the outer rack of source chamber.
191   A 15 keV primary Cs^+ ion beam emitted by a Kimball Physics IGS4 ion gun was
192 utilized to sputter the sample (spot size was approximately 30×27 μm), resulting in
193 negative secondary ions of 10 keV. Electron gun was not used. The secondary sulfur ions

194 were focused to the source slit (60 μm in width) through ion extraction system, and were
195 then transferred through the mass analyzer to the collector. $^{32}S^-$ and $^{34}S^-$ were collected
196 simultaneously by Faraday cups, and were measured using current mode with resistors of
197 10^{12} Ω.

198   All the measurements were carried out in a single session. Analyses of reference
199 materials Ruttan pyrite (primary, $\delta^{34}S_{V\text{-}CDT} = 1.2 \pm 0.1‰$; Crowe and Vaughan, 1996) and
200 Balmat pyrite (secondary, $\delta^{34}S_{V\text{-}CDT} = 15.1 \pm 0.2‰$; Crowe and Vaughan, 1996) were
201 performed typically after every three to five unknowns to correct for instrumental mass
202 fractionation (IMF). Each spot analysis comprised one set, with each set composed of six
203 scans and each scan consisting of ten subcounts of two-second integration. To investigate
204 the effects of Ni and Cu in pyrite on the determination of $^{34}S/^{32}S$, we also measured
205 Norilsk pentlandite and chalcopyrite with bulk $\delta^{34}S_{V\text{-}CDT}$ values of $7.9 \pm 0.2‰$ and $8.0 \pm$
206 $0.2‰$, respectively (Crowe and Vaughan, 1996).

207   All the data of unknowns were calibrated against Ruttan pyrite. The measured
208 $^{34}S^-/^{32}S^-$ ratios are expressed in delta notation as per mil deviations from the standard ratios
209 of Vienna-Canyon Diablo Troilite (V-CDT): $\delta^{34}S_{V\text{-}CDT}$ (‰) =
210 $[(^{34}S/^{32}S)_{unknown}/(^{34}S/^{32}S)_{V\text{-}CDT} - 1] \times 1000$, where $(^{34}S/^{32}S)_{unknown}$ and $(^{34}S/^{32}S)_{V\text{-}CDT}$ are the
211 $^{34}S/^{32}S$ ratios of the unknown and V-CDT, respectively. The internal error of each spot
212 analysis is calculated as $1000 \times 2SE_{unknown}/(^{34}S/^{32}S)_{V\text{-}CDT}$, where $(^{34}S/^{32}S)_{V\text{-}CDT}$ is
213 0.044162589 (Ding et al., 2001) and $2SE_{unknown}$ is two standard error of the $^{34}S/^{32}S$ ratio
214 of unknown. The external error was calculated following $[(1000 \times$
215 $2SE_{unknown}/(^{34}S/^{32}S)_{V\text{-}CDT})^2 + (1000 \times 2SE_{Ruttan}/(^{34}S/^{32}S)_{V\text{-}CDT})^2]^{0.5}$, where $2SE_{Ruttan}$ is two
216 standard error of the $^{34}S/^{32}S$ ratio of Ruttan pyrite.

217

218 **Analytical_isotope ratio mass spectrometry (IRMS)**

219

220   The bulk sulfide isotopic composition analyses were conducted at the Institute of
221 Geochemistry, Chinese Academy of Sciences. Sulfide powder with about 50 μg sulfur
222 was weighed into a tin capsule, which was then put into a reaction vessel filled with
223 oxidant WO_3 and reductant copper. Oxygen was pumped in simultaneously. With the
224 reaction vessel rich in pure oxygen, sulfide and tin were combusted rapidly, producing
225 SO_2 and SO_3. SO_3 was reduced to SO_2 by copper; SO_2 was then introduced into mass
226 spectrometer in a He gas flow for sulfur isotope analysis. The sulfur isotopic
227 compositions were measured using a MAT253 continuous flow Isotope Ratio Mass
228 Spectrometer (Thermo Finnigan) coupled to a Flash EA 2000 Elemental Analyzer. The
229 precision and accuracy were monitored by three IAEA reference materials (Ag_2S):
230 IAEA-S-1 ($\delta^{34}S_{V\text{-}CDT} = -0.3‰$), IAEA-S-2 ($\delta^{34}S_{V\text{-}CDT} = 22.6‰$), and IAEA-S-3
231 ($\delta^{34}S_{V\text{-}CDT} = -32.5‰$).

232

<div align="center">

RESULTS

</div>

After the rapid quench of each experiment, pale-yellow crystals were observed at the low-temperature end of the recovered silica glass tube. Portions of the crystals were adhered to the tube walls whereas the others were movable. The majority of the products are polycrystalline, approximately 2–5 mm in size (Fig. 1); the monocrystals are much smaller cubes, octahedra, etc. The Ni-doped crystals show better crystallization than the undoped ones, and are mostly euhedral (Fig. 1).

Raman spectra

The Raman spectra of the synthesized crystals show bands at ~344 cm^{-1}, ~380 cm^{-1} or 377 cm^{-1}, ~427 cm^{-1} or 430 cm^{-1} (Fig. 2). In most spectra, the strongest peaks are at ~380 cm^{-1}/377 cm^{-1}, and then ~344 cm^{-1}, while the bands at ~427 cm^{-1}/430 cm^{-1} have the lowest intensity (Fig. 2).

Major elements

The contents of major elements in the products are summarized in Table 1, and all the detailed EPMA data are presented in Supplementary Table 1. The S/Fe weight and atomic ratios of PY3 (1.17 ± 0.03, 2.04 ± 0.06, ±2SD), PY4 (1.16 ± 0.02, 2.02 ± 0.04), PY5 (1.15 ± 0.01, 2.01 ± 0.02), and PY6 (1.16 ± 0.01, 2.02 ± 0.02) are close to those of Ruttan pyrite (1.16 ± 0.01, 2.01 ± 0.02) and Balmat pyrite (1.16 ± 0.01, 2.01 ± 0.02). PY5 (undoped), Ruttan pyrite, and Balmat pyrite contain no nickel. PY3 contain the most nickel (0.44 ± 1.18 wt%), followed by PY4 (0.18 ± 0.89 wt%) and PY6 (0.12 ± 0.17 wt%). The Ni concentrations vary among different crystals, 0–2.42 wt% in PY3, 0–2.29 wt% in PY4, and 0–0.36 wt% in PY6; within a single crystal, the range is 0.02–0.48 wt% in PY4, 0.02–1.71 wt% in PY3, and 0.05–0.31 wt% in PY6. The Si, Br, Cl contents in PY3, PY4, PY5, and PY6 determined by EPMA are 0.

Trace elements

The raw data were calibrated against MASS1 for the concentrations of Ni, Cr, Co, Se, and NIST SRM 610 for the contents of Si, Ti, Br, Cl. The trace element concentrations in the products are summarized in Table 2, and all the data are presented in Supplementary Table 2. The MASS1-calibrated concentrations of Ni, Cr, Co, Se for the secondary reference materials STDGL3 and BCR2G are in good accordance with the referenced values (Supplementary Table 2, note that there is no referenced value of Cr for STDGL3, and Se for BCR2G), for instance, the measured Ni concentrations of STDGL3 are 216 to

<div align="right">7</div>

272   232 ppm with referenced value of 247 ppm, and the measured Ni abundances of BCR2G
273   are 11 to 12 ppm with referenced value of 13 ppm. The NIST SRM 610-calibrated Ti and
274   Si concentrations of the secondary reference materials agree well with the referenced
275   values (Supplementary Table 2). For Br and Cl, however, there are slight discrepancies.
276   The Br contents in BCR2G are approximately consistent with the referenced values,
277   whereas the Cl concentrations are higher (289 to 401 ppm vs. 98 ppm/67 ppm). For SY,
278   the measured Br abundances range from 1400 to 4200 ppm, higher than the referenced
279   value of 883 ppm; the measured Cl concentrations are one order of magnitude lower than
280   the referenced value. The discrepancies in BB1a are similar.

281   Silicon is the dominant trace element in both Ruttan pyrite and Balmat pyrite. Ruttan
282   pyrite also contains a small amount of Co, Cl, Ti, Se, and negligible Ni; Balmat pyrite has
283   slight Cl, Ti, Ni, and Co (Table 2; Supplementary Table 2). In the synthesized crystals,
284   silicon is a widespread impurity with relatively constant abundances of 200 to 500 ppm.
285   Other impurities, including Br, Cl, Ti, Cr, Co, are low in concentration, with the
286   exception of several analyses showing slightly higher contents of Br. The dopant Ni is the
287   main trace element in products, except for PY5 that are undoped. The results show
288   significant variations in Ni abundances in both inter- and intra-grains of PY3, PY4, and
289   PY6. The Ni concentration ranges from 39 to 27300 ppm in different PY3 grains, 24 to
290   21700 ppm in PY4 grains, and 57 to 2610 ppm in PY6 grains, respectively. The
291   intra-grain ranges of Ni contents in PY3 grains are 7510–27300 ppm, 387–601 ppm,
292   3000–8860 ppm, 39–164 ppm, 1815–3550 ppm, 1373–2350 ppm, 228–365 ppm, and 596–
293   1216 ppm; those in PY4 grains are 63–509 ppm, 177–439 ppm, 296–450 ppm, 199–316
294   ppm, 1286–2930 ppm, 656–729 ppm, and 463–475 ppm; those in PY6 grains are 1148–
295   1840 ppm, 310–753 ppm, 57–426 ppm, 355–1772 ppm, 995–2610 ppm, 1450–2020 ppm,
296   and 622–1280 ppm. EPMA-derived Ni contents and LA-ICPMS-obtained Ni
297   concentrations are in good accordance (Fig. 3).

298

299   **Sulfur isotopic composition_SIMS**

300

301   The count rates (counts per second, CPS) of $^{32}S^-$ and $^{34}S^-$ are 0.9–1.4 GHz and 40–60
302   MHz, respectively. The 45 analyses of Ruttan pyrite yield a mean $\delta^{34}S$ value of $1.2 \pm 0.6‰$
303   (2SD), and the 10 analyses of Balmat pyrite have a mean $\delta^{34}S$ value of $15.4 \pm 0.7‰$
304   (2SD). The internal error and external error (2σ) of $\delta^{34}S$ for each spot analysis range from
305   0.1 to 0.6 ‰ and 0.6 to 0.9 ‰, respectively.

306   The SIMS sulfur isotope data are summarized in Table 3, and all the data are listed in
307   Supplementary Table 3. The 26 spot analyses performed on 11 different PY3 grains show
308   $\delta^{34}S$ values of 16.2 to 18.2‰, averaging at 17.3‰ (2SD = ±0.9‰) (Fig. 4). The $\delta^{34}S$ ranges
309   of the eight grains with multiple analyses are 16.2–17.6‰, 16.5–17.7‰, 16.7–17.4‰,
310   16.9–18.0‰, 17.1–17.7‰, 17.4–18.2‰, 17.2–17.8‰, and 17.4–17.5‰, respectively. The

8

311   26 spot analyses on 14 different PY4 crystals exhibit $\delta^{34}S$ values ranging from 17.0 to
312   18.7‰, yielding a mean of 17.7‰ (2SD = ±0.8‰) (Fig. 4). The seven monocrystals with
313   multiple analyses show $\delta^{34}S$ values varying from 17.2 to 18.4‰, 17.5 to 17.6‰, 17.0 to
314   17.8‰, 17.5 to 17.6‰, 17.7 to 18.2‰, 18.0 to 18.7‰, and 17.4 to 17.7‰, respectively.
315   The 32 spot analyses conducted on 14 PY5 crystals display $\delta^{34}S$ values of 16.6 to 18.7‰,
316   with a mean of 17.9‰ (2SD = ±0.8‰) (Fig. 4). The eight single grains show $\delta^{34}S$ values
317   ranging from 18.1 to 18.7‰, 16.6 to 18.1‰, 17.4 to 17.7‰, 17.2 to 18.2‰, 17.4 to 18.2‰,
318   17.9 to 18.0‰, 17.7 to 18.2‰, and 17.8 to 18.1‰, respectively. The 22 spot analyses on
319   eight PY6 grains show $\delta^{34}S$ values varying from17.0 to 18.4 ‰, yielding a mean of 17.7‰
320   (2SD = ±0.6‰) (Fig. 4). The $\delta^{34}S$ variations of the seven monocrystals are 17.8–18.0‰,
321   17.0–17.9‰, 17.7–18.0‰, 17.4–18.1‰, 17.3–17.6‰, 17.9–18.4‰, and 17.3–18.0‰,
322   respectively. The Norilsk pentlandite shows $\delta^{34}S$ values (calibrated to Ruttan pyrite) of 6.2
323   to 7.1‰ with a mean of 6.6 ± 0.6‰ (2SD), thus an average discrepancy of −1.3‰
324   compared with the bulk $\delta^{34}S$ value (7.9 ± 0.2‰, Crowe and Vaughan, 1996). The Ruttan
325   pyrite-calibrated $\delta^{34}S$ values of Norilsk chalcopyrite range from 8.1 to 9.1‰, averaging at
326   8.5‰ (2SD = ±0.5‰). Compared with the bulk $\delta^{34}S$ value of 8.0 ± 0.2‰ (Crowe and
327   Vaughan, 1996), the average bias is 0.5‰.
328
329   **Sulfur isotopic composition_IRMS**
330
331   All data were reported in standard delta notation ($\delta^{34}S$) relative to V-CDT. The
332   precision is better than 0.2‰ (1σ). The three aliquots of PY3, PY5, and the two aliquots
333   of PY6 show relatively consistent sulfur isotopic compositions, with $\delta^{34}S$ values of 17.8 ±
334   0.2‰ (2SD), 18.2 ± 0.3‰, and 18.1 ± 0.1‰, respectively (Table 4). The products of PY4
335   exhibit slight dispersion, with $\delta^{34}S$ values ranging from 17.9‰ to 18.8‰ (18.3 ± 0.9‰)
336   (Table 4).
337
338   DISCUSSION
339
340   **Products**
341
342   Compositionally, the products have S/Fe weight and atomic ratios of 1.15–1.17 and
343   2.01–2.04, respectively (Table 1), similar to that of natural Ruttan pyrite (1.16, 2.01) and
344   Balmat pyrite (1.16, 2.01), corresponding to a chemical formula of FeS_2 (ideal S/Fe ratio
345   of 2 and weight ratio of 1.15). The slight deviations can be attributed to the
346   impurities/trace elements substitutions for Fe and S, including Ni, Si, Co, Cr, Ti, Cl, and
347   Br. The atomic ratios of 2.01–2.04 indicate more Fe deficiencies.
348   Nickel is the dopant; Si should be derived from the silica glass tube that is the
349   chamber of CVT reaction; Co, Cr, and Ti are most likely to be inherited from the

9

350   impurities in nickel reagent or contamination from other sources; Br should be
351   incorporated from the transport agent $FeBr_3$, and Cl is most likely contributed by the
352   impurities in $FeBr_3$ starting material (99%). Bromine (below detection limit to 270 ppm)
353   and/or silicon (1600 to 14600 ppm) have been reported as common unintentional
354   impurities detected by PIXE (Lehner et al., 2012) and Rutherford backscattering (Tomm
355   et al., 1995). The incorporation of Br and Cl impurities in pyrite crystal has been
356   attributed to $(S-Cl)^{2-}$ and $(S-Br)^{2-}$ radical-ions in the crystal structure substituting for S_2^{2-}
357   dumb-bells (Fiechter et al., 1986).
358   In Raman spectra of the products, the three bands are at ~344 cm^{-1}, ~380 cm^{-1}/377
359   cm^{-1}, ~427 cm^{-1}/430 cm^{-1} (Fig. 2), consistent with the three mostly observed bands of
360   pyrite (anisotropic) (Mernagh and Trudu, 1993), while distinct from those of marcasite
361   (polymorph of pyrite) with characteristic bands at 324 cm^{-1}, 387 cm^{-1}, and 532 cm^{-1}
362   (Mernagh and Trudu, 1993). The band at ~380 cm^{-1}/377 cm^{-1} is assigned to the one
363   totally symmetric mode A_g (in-phase stretching vibrations of S_2 dumb-bells); the bands at
364   ~344 cm^{-1} and ~427 cm^{-1}/430 cm^{-1} correspond to the doubly degenerate mode E_g
365   (libration of S_2 dumb-bells) and the triply degenerate mode F_g (various librational and
366   stretching motions or their combinations of S_2 dumb-bells), respectively (Sourisseau et al.,
367   1991).
368   Combining the abovementioned chemical and structural characteristics, in addition to
369   the pale-yellow color and cubic and octahedral crystal forms, the products are FeS_2
370   pyrite.
371
372   **The CVT reaction**
373
374   The CVT reaction synthesizing pyrite with FeS and S as the starting materials and
375   $FeBr_3$ as the transport agent in this study can be simplified into five steps. At the hot end
376   of the silica glass tube, solid sulfur powders firstly sublimed to sulfur gases. The sulfur
377   gas was then reacted with FeS, forming FeS_2 (Equation 1). The newly formed solid phase
378   FeS_2 was subsequently reacted with $FeBr_3$ gas, generating transportable $FeBr_2$ and sulfur
379   gases (Fiechter et al., 1986; forward equation of Equation 2). $FeBr_2$ and sulfur gases were
380   then transported towards the cold end of the tube driven by the temperature and
381   concentration gradients. At the cold end, $FeBr_2$ and sulfur gases reacted, yielding solid
382   phase FeS_2 and $FeBr_3$ gas (Fiechter et al., 1986; backward equation of Equation 2).
383   $FeS(s) + 1/2 S_2(g) \rightarrow FeS_2(s)$ (1)
384   $FeS_2(s) + 2FeBr_3(g) \rightleftharpoons 3FeBr_2(g) + S_2(g)$ (2)
385   For CVT reactions employing chlorine or bromine as the transport agent, the total
386   pressure has been suggested to be approximately the dissociation pressure of pyrite
387   (Fiechter et al., 1986). At temperatures of ~650 to ~550 °C (this study), the pressure,
388   according to Fig. 3b in Fiechter et al. (1986), is lower than the threshold of 3 bar, below

10

389 which the gas motion from hot to cold end is via diffusion rather than convection
390 (Schmidt et al., 2013 and references therein).

391   For the dopant Ni, as no other phase(s) (e.g., NiS_x) other than pyrite is observed in
392 the products at the cold end, additionally, some NiS_x phase(s) are stable under the
393 conditions of the cold end (e.g., Waldner and Pelton, 2004; Kitakaze et al., 2011), thus it
394 is less likely that metal nickel was reacted with sulfur gases forming NiS_x (Equation 3),
395 and then NiS_x was reacted with $FeBr_3$ generating transportable $NiBr_2$ gases (Equation 4)
396 at the hot end; instead, it is more likely that metal nickel was reacted directly with $FeBr_3$
397 forming $NiBr_2$ gases (Equation 5). Arriving at the cold end, $NiBr_2$ and $FeBr_2$ gases
398 reacted, and nickel was deposited as metal nickel storing in the crystal structure of pyrite.
399 $Ni(s) + x/2S_2(g) \rightarrow NiS_x(s)$ (3)
400 $NiS_x(s) + 2FeBr_3(g) \rightleftharpoons 2FeBr_2(g) + NiBr_2(g) + x/2S_2(g)$ (4)
401 $Ni(s) + 2FeBr_3(g) \rightleftharpoons 2FeBr_2(g) + NiBr_2(g)$ (5)

402

403 **Heterogeneity of Ni in CVT-synthesized pyrite**

404

405   The intended doped Ni concentrations (calculated as bulk based on the amounts of
406 FeS, S, Ni) are 3.4 wt% in PY3, 6.5 wt% in PY4, and 12.0 wt% in PY6 (the amounts of
407 starting materials are listed in Supplementary Table 4). However, the Ni contents of the
408 pyrite products show significant heterogeneity among and within grains (Fig. 5): 39 to
409 27300 ppm in PY3, 24 to 21700 ppm in PY4, and 57 to 2610 ppm in PY6. The lower
410 maximum Ni concentration value measured in PY6 is most likely a sampling bias, with
411 the spot analyses being unintentionally concentrated in regions/grains with low to
412 medium Ni abundances.

413   Some previous studies have also measured the concentrations of dopant(s) in
414 CVT-synthesized pyrite. Lehner et al. (2012) analyzed the bulk concentrations of trace
415 elements in CVT-synthesized pyrite using ICPMS and IC-AES, and measured in situ the
416 abundances of Ni and Co using SIMS and the contents of As by Rutherford
417 backscattering; however, the intra- and inter-grain variations of the concentrations were
418 not reported. Lehner et al. (2006) determined the concentrations of Ni, Co, and As in
419 CVT-grown pyrite using LA-ICPMS, and the results show variations of up to 429 ppm
420 for Ni, 2198 ppm for Co, and 680 ppm for As in pyrite crystals synthesized with the same
421 amount of dopants.

422   Tomm et al. (1995) pointed out that it is necessary to adapt the growth velocity of
423 pyrite crystals to the diffusion conditions for the dopant element. They attributed the
424 inhomogeneous dopant distribution to the high growth rate of pyrite crystals. In the
425 CVT-grown pyrite crystals of this study, voids are occasionally observed (Figs. 1 and 5),
426 which can arise from high growth rate. The fast growth rate of pyrite crystals at the cold
427 end with uncoupled $NiBr_2$ gas motion from hot end to cold end may thus be the cause of

11

428   the significant variations of Ni contents.

429

Homogeneity of $^{34}S/^{32}S$ in CVT-synthesized pyrite

431

432   The undoped PY5 have a mean $\delta^{34}S$ value of 17.9‰, with 2SD of 0.8‰. PY3, PY4,

433   and PY6 have mean $\delta^{34}S$ values of 17.3 ± 0.9‰ (2SD), 17.7 ± 0.8‰, and 17.7 ± 0.6‰,

434   respectively.

435   The ranges of $\delta^{34}S_{V\text{-}CDT}$ values of pyrite reference materials (Ruttan pyrite, Balmat

436   pyrite, Sierra pyrite, Sonora pyrite, Maine pyrite, Isua278474 pyrite, Isua248474 pyrite,

437   PPP-1 pyrite, Py-1 pyrite, Car111 pyrite, and Gabon pyrite) applied to the determination

438   of sulfur isotopic composition in previous studies (Philippot et al., 2007; Cabral et al.,

439   2013; Farquhar et al., 2013; Ireland et al., 2014; LaFlamme et al., 2016; Gallagher et al.,

440   2017; Ward et al., 2017; Drake et al., 2018; Philippot et al., 2018; Teles et al., 2020; Chen

441   and Campbell, 2021; Li et al., 2018; Li et al., 2021; Liu et al., 2021) are summarized in

442   Table 5, and all the compiled data and the related references are presented in

443   Supplementary Table 5. The homogeneity of the $\delta^{34}S_{V\text{-}CDT}$ of CVT-synthesized pyrite in

444   this study (2SD = 0.6−0.9‰) is comparable to or even better than that of Balmat pyrite

445   (2SD = 0.2−1.4‰), Maine pyrite (2SD = 0.8−1.5‰), Isua278474 pyrite (2SD =

446   0.5−1.0‰), Isua248474 pyrite (2SD = 0.9‰), Py-1 pyrite (2SD = 1.1‰), Car111 pyrite

447   (2SD = 2.5‰), and Gabon pyrite (2SD = 1.1‰) (Table 5), which were used as secondary

448   reference materials in the literature. Nevertheless, compared with the relatively

449   homogeneous $\delta^{34}S_{V\text{-}CDT}$ of primary reference materials such as Ruttan pyrite (2SD =

450   0.1−0.6‰), Sierra pyrite (2SD = 0.2‰), Sonora pyrite (2SD = 0.2‰), and PPP-1 pyrite

451   (2SD = 0.3‰), the $\delta^{34}S_{V\text{-}CDT}$ of the CVT-grown pyrite in this study are still slightly

452   dispersed.

453

Possible sources of $^{34}S/^{32}S$ variation_$^{34}S/^{32}S$ heterogeneity in starting materials

455

456   The starting FeS powder is relatively homogeneous in $^{34}S/^{32}S$, with an average $\delta^{34}S$

457   value of 19.0‰ and 2SD of 0.3‰; by comparison, the $^{34}S/^{32}S$ of sulfur powder shows

458   slight heterogeneity, with $\delta^{34}S$ values varying from 16.9‰ to 17.8‰ (2SD = 0.9‰)

459   (Supplementary Table 8).

460   For PY3 pyrites, all sulfur is derived from S powder, thus the $^{34}S/^{32}S$ heterogeneity in

461   the starting S powder can be inherited by the synthesized pyrite products. For PY4, PY5,

462   and PY6 pyrites, the $\delta^{34}S$ values are determined by the molar ratio of the FeS

463   powder-derived sulfur ($S_{FeS\ powder}$) to the S powder-derived sulfur ($S_{S\ powder}$) in pyrite

464   products, as well as the $\delta^{34}S$ values of the starting FeS and S powders. One possibility is

465   that the reactions strictly and simply follow Equations 1 and 2, i.e., a $S_{FeS\ powder}/S_{S\ powder}$

466   ratio of 1:1. In this case, the pyrite products can have $\delta^{34}S$ values of 17.9 to 18.5‰,

467 which agree with the measured values (both bulk and in-situ) considering the associated
468 uncertainties. However, this is not the only possibility, because after all, the actual
469 reactions are much more complicated, e.g., in Equation 2, the backward reaction
470 depositing pyrite at the cold end can potentially involve more sulfur gases stemming from
471 S powder. Therefore, the $S_{FeS\ powder}/S_{S\ powder}$ ratio can be various.
472   For both possibilities, to increase the homogeneity of CVT-synthesized pyrite, one
473 effective way is suppressing the heterogeneity of the starting materials. For the latter
474 possibility, an additional potentially effective measure is using starting FeS and S
475 powders with the same $\delta^{34}S$.
476
Possible sources of $^{34}S/^{32}S$ variation_kinetic fractionations during CVT reaction
478
479   The majority of the pyrite crystals show an increasing trend in $\delta^{34}S$ from one side to
480 the other side of the grain (Supplementary Figs. 1 and 2). It is noteworthy that pyrite
481 crystals during CVT reaction grew on the wall of silica glass tube, i.e., the crystals grew
482 from one side to the other. Therefore, another possible source is the kinetic fractionations
483 during the five main steps of CVT reaction: (1) sublimation of solid sulfur, (2)
484 combination of solid FeS with sulfur gas forming solid FeS_2, (3) transformation of solid
485 FeS_2 to $FeBr_2$ and S_2 gases, (4) transport of $FeBr_2$ and S_2 gases across the tube, and (5)
486 deposition of $FeBr_2$ and S_2 gases to solid FeS_2.
487   Theoretically, according to the Arrhenius equation $k = Ae^{-Ea/RT}$ (k is reaction rate
488 constant, A is frequency or pre-exponential factor, E_a is activation energy, R is gas constant,
489 T is temperature), at the same temperature, light isotope ^{32}S has lower value of E_a, thus
490 higher reaction rate constant, and reacts more rapidly than heavy isotope ^{34}S. Therefore,
491 the chemical reactions (combination of solid phase FeS with sulfur gas, transformation of
492 solid phase FeS_2 to $FeBr_2$ and S_2 gases, and deposition of $FeBr_2$ and S_2 gases to solid
493 phase FeS_2) can potentially induce $^{34}S/^{32}S$ isotopic fractionation, which results in lower
494 $\delta^{34}S$ values of earlier-deposited pyrite crystals and higher $\delta^{34}S$ of later-precipitated ones.
495 In addition to the effects of mass difference of isotopes, the condensation site (e.g., close
496 to the source, intermediate, and at the far cold end) of pyrite crystals is also an important
497 factor, as specific sites correspond to different temperatures. It has been theoretically
498 demonstrated that during condensation the saturation vapor pressure ($P_{j,sat}$) of the species
499 containing the isotopes of interest is a significant determining factor for the net isotope
500 fractionation (α_{cond}) (Equation 43 in Bourdon and Fitoussi, 2020), and $P_{j,sat}$ is a function
501 of temperature (Davis and Richter, 2014). Therefore, the various condensation sites are
502 also a source of $\delta^{34}S$ variation.
503   Apart from the chemical reactions of CVT, the gas motion (predominantly $FeBr_2$ and
504 S_2 gases) from hot end to cold end, which is a process of diffusion rather than convection
505 as discussed in Section 4.2, is also a plausible contributor to the $\delta^{34}S$ heterogeneity. As

13

506   has been experimentally demonstrated recently, thermal (Soret) diffusion does induce
507   sulfur isotope fractionation, up to 2.1‰ for δ^{34}S at a temperature gradient of ~175 °C
508   under conditions of 1500 °C and 1.45 GPa for basaltic substrate with pyrite sulfur (Fortin
509   et al., 2019). The magnitude of thermal diffusion-induced isotope fractionation has been
510   quantified experimentally and theoretically, for instance,

511   $\Delta^{X}M = -\int_{T_0}^{T} \Delta S_T dT$ (Huang et al., 2010)

512   $\Delta^{X}M \approx A\ln(T/T_0)$ (Li and Liu, 2015)

513   where $\Delta^{X}M$ is the fractionation of $\delta^{X}M$, X is the mass of heavy isotope, T_0 is the
514   reference temperature, T is the temperature at another position, S_T is the Soret coefficient,
515   $\Delta S_T = (S_T)_{m*} - (S_T)_m$, $A = -3/2\ln(m^*/m) - \ln(\sigma/\sigma^*)$, m^* and m are the heavy and light
516   isotopes, respectively, σ is the symmetry number. It is difficult to determine the exact
517   sulfur isotopic fractionation at a given T due to the lack of parameter values such as S_T of
518   sulfur species S_2 under the conditions of this study. Nevertheless, the equations indicate
519   that the degree of such fractionation is dependent on T, i.e., condensation site of pyrite
520   crystals in the case of CVT.
521   Collectively, kinetic isotope fractionations stemming from the chemical reactions and
522   thermal diffusion during CVT as well as different condensation sites potentially
523   contributed to the δ^{34}S heterogeneity of pyrite, although at present it is difficult to
524   quantitatively estimate the total kinetic isotopic fractionations during the CVT reaction due
525   to the lack of pertinent determined parameters.
526
527   **Possible sources of ^{34}S/^{32}S variation_matrix effects**
528
529   In this study, the in-situ δ^{34}S values of undoped PY5 show deviations of −0.6 to 0.5‰
530   (Δ^{34}S = δ^{34}S$_{SIMS(in-situ)}$ − δ^{34}S$_{IRMS(bulk)}$) from the bulk δ^{34}S value (Supplementary Table 6;
531   Fig. 6), which can be attributed to the analytical uncertainties of both in-situ and bulk
532   δ^{34}S (2σ = 0.7 to 0.9‰, calculated following 2σ = [(external error of in-situ δ^{34}S)^2 +
533   (analytical error of bulk δ^{34}S)^2]$^{0.5}$). For Ni-doped pyrites with a range of concentrations of
534   Ni, the magnitudes of the discrepancies between in-situ and bulk δ^{34}S values are −0.9 to
535   0.4‰ for PY3 (2σ = 0.7 to 0.9‰), −1.0 to 0‰ for PY4 (2σ = 0.7 to 0.9‰), and −0.9 to
536   0.3‰ for PY6 (2σ = 0.8 to 0.9‰). The majority of the offsets are within the associated
537   uncertainties, with the exception of four data points displaying larger magnitudes of Δ^{34}S
538   (−0.8‰, −0.9‰, −1.0‰, −1.0‰) than the related uncertainties (0.7‰, 0.7‰, 0.8‰,
539   0.7‰). Such deviations are likely to arise from matrix effects.
540   The matrix effects of impurities in pyrite on the determination of ^{34}S/^{32}S have rarely
541   been investigated. Riciputi et al. (1998) studied the effects of instrumental parameters,
542   including primary ion beam, secondary ion energy, and polarity on the measurements of
543   ^{34}S/^{32}S using a modified Cameca 4f ion microprobe. They found that the bias for sulfur

14

544   isotope measurement is small (several per mil) compared with that for carbon and oxygen

545   isotopes (tens of per mil) when using Cs^+ as primary ions.

546   Regression of all the data points for PY3, PY4, and PY6 (excluding the two with

547   positive $\Delta^{34}S$) as well as the data point for Norilsk pentlandite (average Ni content of 38.2

548   wt%, Supplementary Table 7, and $\Delta^{34}S$ of −1.3‰ calibrated to Ruttan pyrite,

549   Supplementary Table 3) yields an empirical calibration equation of $\Delta^{34}S$(‰) = −0.59 ×

550    $Ni(wt\%)^{0.27}$ (R^2 = 0.3), where $\Delta^{34}S$ is the discrepancy between in-situ and bulk $\delta^{34}S$

551   values, Ni is the concentration of nickel in pyrite. Although pentlandite has a different

552   crystal structure compared with pyrite, we still roughly view it as the high-Ni pyrite end

553   member based on similar count rate (CPS) of secondary sulfur ions (slightly lower,

554   Supplementary Table 3; Fig. 6). It can be predicted from the above equation that the

555   matrix effects of nickel in pyrite are restricted within a small magnitude (around −1‰).

556   Admittedly, the small magnitudes of $\Delta^{34}S$ corresponding to low Ni contents (<0.26 wt%)

557   show large uncertainties, and the pertinent data points are quite scattered. Regression

558   incorporating only data points with Ni concentration higher than 0.26 wt.% yields a line

559   with an equation of $\Delta^{34}S$ (‰) = −0.02Ni (wt%) − 0.69 (R^2 = 0.6). However, the line and

560   the curve are close, with the maximum discrepancy being approximately 0.3‰

561   (calculated from $−0.02Ni − 0.69 + 0.59 × Ni^{0.27}$), therefore, we still use the equation of

562    $\Delta^{34}S = −0.59 × Ni^{0.27}$ for empirical calibration.

563   When calibrating other Fe- and S-bearing sulfides (chalcopyrite, arsenopyrite,

564   pyrrhotite) against Ruttan pyrite, the biases ($\Delta^{34}S = \delta^{34}S_{SIMS} − \delta^{34}S_{IRMS}$) vary from sulfide

565   to sulfide in both magnitude and sign (Supplementary Tables 9 and 10). The Norilsk

566   pentlandite shows a bias of −1.3 ± 0.6‰ (2SD) with the same sign as that of Ni-bearing

567   pyrite. The YJS65 arsenopyrite (Xie et al., 2019) displays a larger bias of −2.3 ± 0.8‰

568   (2SD), and one session even gives a bias up to −5.0‰. In contrast, the Norilsk

569   chalcopyrite exhibits a positive bias of 0.5 ± 0.6‰ (2SD), with the bias of only one

570   session being 2.7‰. In comparison, the bias of pyrrhotite is more intricate. In this study,

571   Anderson pyrrhotite displays a positive bias of 0.4 ± 0.3‰ (2SD) and a negative bias of

572   −0.7 ± 0.5‰ (2SD), YP136 pyrrhotite (Li et al., 2019) shows a positive bias of 1.6 ± 0.8‰

573   (2SD); in Liu et al. (2020), Anderson pyrrhotite exhibits a positive bias of 0.3 ± 0.5‰

574   (2SD) and a negative bias of −0.3 ± 0.4‰ (2SD). Such complex biases of pyrrhotite may

575   be attributed to various S/Fe ratios in different pyrrhotite grains.

576   The respective negative and positive biases ($\Delta^{34}S$) of arsenopyrite and chalcopyrite

577   correlate with lower and higher sulfur ion yields ($^{32}S^-$, CPS) and sulfur contents, higher

578   and lower iron contents (Fig. 7a, c, d). However, when involving pentlandite and

579   pyrrhotite, there are no correlations as a whole. Nevertheless, the bias shows a good

580   correlation with the discrepancy between the sulfur ion yields of other sulfides and that of

581   Ruttan pyrite in the same SIMS analytical session (Fig. 7b). The kinetic mechanism of

582   Eiler et al. (1997) can be used to explain the bias of chalcopyrite ($CuFeS_2$), as copper has

15

583   a higher atomic mass of 63.5 amu than iron (55.8 amu). During sputtering, chalcopyrite

584   transfers kinetic energy more efficiently to ^{34}S than to ^{32}S compared with pyrite (FeS$_2$),

585   thus giving rise to larger $\delta^{34}S$ values. However, this mechanism cannot account for the

586   biases of arsenopyrite (FeAsS) and pentlandite [(Ni$_x$Fe$_y$)$_9$S$_8$].

587

588   **IMPLICATIONS**

589

590   Based on the relatively uniform distribution of $^{34}S/^{32}S$, the CVT-synthesized pyrite

591   has the potential to be applied as reference material for the *in-situ* measurement of sulfur

592   isotopes using techniques such as SIMS and LA-ICPMS. The inevitable impurities (e.g.,

593   Br, Cl, Si) can potentially have effects on the sputtering of the target mineral surface by

594   primary ions of SIMS, thus the secondary ion yields and instrumental mass fractionation

595   (i.e., mineral chemistry- and/or structure-induced matrix effects, Ireland, 2004 and

596   references therein). Ruttan pyrite and Balmat pyrite contain similar low amounts (up to

597   several hundred ppm) of Si and Cl to CVT-grown pyrite as well as other trace elements

598   (Table 2), however, such matrix effects have not been observed. Previous reported matrix

599   effects caused by chemical impurities are of major elements (e.g., Rollion-Bard and

600   Marin-Carbonne, 2011; Vho et al., 2020). As such, given the low concentrations of these

601   impurities in CVT-synthesized pyrite, such effects can be negligible. One exception is

602   that high concentrations of Br (up to 31200 ppm) are observed in a few grains in this

603   study. Further investigations are needed to assess whether such high contents of Br give

604   rise to observable matrix effects in sulfur isotope measurements by SIMS.

605

606   **CONCLUDING REMARKS**

607

608   This study synthesized pyrite crystals via Chemical Vapor Transport (CVT) reaction.

609   The pyrites contain traces of impurities such as Si, Br, Cl, Co, Cr, Se, Ti, which can be

610   derived from the starting materials and silica glass reaction tube. The nickel

611   concentrations of nickel-doped pyrites are heterogeneous, at both inter- and intra-grain

612   scales, which can be attributed to the high growth rate of pyrite crystals with uncoupled

613   motion rate of NiBr$_2$ gas. In contrast, the sulfur isotopic compositions ($\delta^{34}S$) of these

614   pyrites are relatively homogeneous despite slightly dispersed compared with currently

615   used primary reference materials (e.g., Ruttan pyrite). The variations in $\delta^{34}S$ can arise

616   from the slight heterogeneity of $\delta^{34}S$ in starting materials, the kinetic isotopic

617   fractionations during the chemical and physical processes of CVT reaction and different

618   condensation sites in tubes, as well as the minor matrix effects of nickel for SIMS

619   analysis. An empirical equation was obtained for the calibration of the matrix effects of

620   nickel in pyrite: $\Delta^{34}S$ (‰) $= -0.59 \times$ Ni(wt%)$^{0.27}$. Based on the homogeneity of $^{34}S/^{32}S$,

621   CVT-grown pyrite has the potential to be used as reference material for *in-situ*

16

622   measurement of sulfur isotopes in pyrite using techniques such as SIMS and LA-ICPMS.

833

834   Fig. 1. Photographs (a–d) and BSE images (e–h) of the crystals synthesized by CVT
835   method in this study. Note that Ni-doped PY3, PY4, and PY6 are larger in size than
836   undoped PY5. The white bar in (a) to (d) is for 2 mm. The gradual change in brightness
837   horizontally in (e) to (h) is due to SEM instrumental problems rather than the crystals per
838   se.

839

840   Fig. 2. Raman spectra of typical crystals PY3, PY4, PY5, and PY6. Note that the spectra
841   of wavenumber higher than 1000 cm^{-1} are not plotted because they are featureless.

842

843   Fig. 3. Plot of nickel contents derived from EPMA and LA-ICPMS. The error bar is the
844   value of 2SE.

845

846   Fig. 4. δ^{34}S variations of PY3, PY4, PY5, and PY6, along with the corresponding bulk δ^{34}S
847   values obtained by IRMS (grey line). The error bar is external error ($\pm 2\sigma$). The thickness of
848   the grey line is the value of 2SE, which takes the variation of bulk δ^{34}S and the uncertainty
849   of IRMS measurement into account.

850

851   Fig. 5. BSE images of typical PY3, PY4, PY5, and PY6 CVT-synthesized pyrite grains
852   with nickel concentrations and δ^{34}S values. Note the heterogeneity of Ni abundances
853   (yellow, ppm) and the homogeneity of δ^{34}S (white, ‰) among polygrains and within
854   monograins. Spot size is much smaller than the circles. Again the gradual change in
855   brightness horizontally in these BSE images is due to SEM instrumental problems rather
856   than the crystals per se.

857

858   Fig. 6. Plot of nickel contents obtained by LA-ICPMS (transformed to wt.%) vs. the
859   deviation magnitudes of in-situ δ^{34}S values from bulk δ^{34}S values (Δ^{34}S = δ^{34}S$_{\text{in-situ}}$ −
860   δ^{34}S$_{\text{bulk}}$). For curve fitting, the data points of PY5 and those with positive Δ^{34}S values are
861   excluded; the data point (38.2 wt.%, −1.3‰, average values) for the Norilsk pentlandite is
862   incorporated. The average error of Δ^{34}S (1σ) is 0.4‰, which includes the external error of
863   in-situ δ^{34}S and the error of bulk δ^{34}S; the average error of Ni content (1σ = 0.0038 wt.%)
864   of pyrite is too small to be displayed; the average error (1σ) of Ni content of Norilsk
865   pentlandite is displayed.

866

867   Fig. 7. (a) Plot of secondary sulfur ion (^{32}S^{-}) yield (CPS, counts per second) vs. the
868   magnitudes of δ^{34}S bias (Δ^{34}S = δ^{34}S$_{\text{in-situ}}$ − δ^{34}S$_{\text{bulk}}$), δ^{34}S$_{\text{in-situ}}$ was obtained by calibration
869   against Ruttan pyrite. (b) Plot of discrepancy of secondary sulfur ion yield between other
870   sulfides and Ruttan pyrite in the same session [(CPS$_{32S-}$)$_{\text{other sulfide}}$ − (CPS$_{32S-}$)$_{\text{Ruttan Pyrite}}$)]

871 vs. the magnitudes of Δ^{34}S. Anderson pyrrhotite_BF are from this study, and Anderson
872 pyrrhotite_LL are from Liu et al. (2020). All the related data are listed in Supplementary
873 Tables 9 and 10. (c) Plot of S content in sulfides vs. Δ^{34}S. (d) Plot of Fe content in
874 sulfides vs. Δ^{34}S. The sulfur and iron contents in Anderson Pyrrhotite are cited from
875 Kozdon et al. (2010), those in YP136 Pyrrhotite are cited from Li et al. (2019), those of
876 YJS65 Arsenopyrite and Norilsk Chalcopyrite are calculated from their ideal formulae.
877 The uncertainty of Δ^{34}S incorporated that of both δ^{34}S$_{in\text{-}situ}$ and δ^{34}S$_{bulk}$.

878

879 Supplementary Fig. 1. The map of Mount Z7100 with PY3 and PY4 pyrite grains. Also
880 shown are the δ^{34}S values (‰, green numbers) and Ni contents (ppm, blue numbers). The
881 white ellipse only illustrates the location of each spot analysis, and the size is not the
882 actual spot size. The yellow dashed lines with arrow are the direction with an increasing
883 trend of δ^{34}S, which can be pyrite crystal growth direction.

884

885 Supplementary Fig. 2. The map of Mount Z7102 with PY5 and PY6 pyrite grains. Also
886 shown are the δ^{34}S values (‰, green numbers) and Ni contents (ppm, blue numbers). The
887 white ellipse only illustrates the location of each spot analysis, and the size is not the
888 actual spot size. The yellow dashed lines with arrow are the direction with an increasing
889 trend of δ^{34}S, which can be pyrite crystal growth direction.
