21 Abstract

Incorporation of ferric iron in mantle silicates stabilizes different crystal structures and changes 22 23 phase transition conditions, thus impacting seismic wave speeds and discontinuities. In MgSiO₃-Fe₂O₃ mixtures, recent experiments indicate the coexistence of fully oxidized iron-rich 24 $(Mg_{0.5}Fe_{0.5}^{3+})(Fe_{0.5}^{3+}Si_{0.5})O_3$ with Fe-poor silicate (wadsleyite or bridgmanite) and stishovite at 25 15 to 27 GPa and 1773 to 2000 K, conditions relevant to subducted lithosphere in the Earth's 26 transition zone and uppermost lower mantle. X-ray diffraction measurements show that 27 $(Mg_{0.5}Fe_{0.5}^{3+})(Fe_{0.5}^{3+}Si_{0.5})O_3$ recovered from these conditions adopts the R3c LiNbO₃-type 28 structure, which transforms to the bridgmanite structure again between 18.3 GPa and 24.7 GPa at 29 300 K. Diffraction observations are used to obtain the equation of state of the LiNbO₃-type phase 30 up to 18.3 GPa. These observations combined with multi-anvil experiments suggest that the 31 stable phase of $(Mg_{0.5}Fe_{0.5}^{3+})(Fe_{0.5}^{3+}Si_{0.5})O_3$ is bridgmanite at 15-27 GPa, which transforms on 32 decompression to LiNbO₃-type structure. Our calculation revealed that ordering of the ferric ion 33 reduces the kinetic energy barrier of the transition between $(Mg_{0.5}Fe_{0.5}^{3+})(Fe_{0.5}^{3+}Si_{0.5})O_3$ LiNbO₃ 34 structure and bridgmanite relative to the MgSiO₃ akimotoite-bridgmanite system. Dense Fe³⁺-35 rich bridgmanite structure is thus stable at substantially shallower depths than MgSiO₃ 36 bridgmanite and would promote subduction. 37

38 **1 Introduction**

Mineralogical differences due to chemical heterogeneity in the mantle are crucial for 39 understanding the dynamics of mantle convection and driving forces for plate tectonics (Stixrude 40 and Lithgow-Bertelloni 2012; Faccenda and Dal Zilio 2017). The average oxygen fugacity of the 41 upper mantle has been underestimated (Cottrell and Kelley 2011), and orders of magnitude 42 heterogeneity in mantle oxygen fugacity suggest that both subduction and plumes oxidize the 43 mantle (Cottrell and Kelley 2013; Moussallam et al. 2019; Cottrell et al. 2021). Local iron 44 enrichment and high oxygen fugacity may be also found in regions containing subducted basalt 45 and hematite-rich sediment. These variations in oxidation of the mantle may impact the stability 46 and equilibrium composition of major mantle minerals (e.g. Gu et al. 2016), with corresponding 47 effects on seismic velocities and dynamics of downwelling slabs and upwelling plumes. 48

49 Recent experiments (Wang et al. 2021; Chanyshev et al. 2023) indicate that under 50 oxidizing conditions in the transition zone and uppermost lower mantle, Fe^{3+} may partition out of

dominant silicates wadsleyite, ringwoodite, and bridgmanite into a separate dense phase. In bulk 51 52 compositions with 90-93% MgSiO₃ and 7-10% Fe₂O₃, experiments at 15-27 GPa and 1773-2000 K produce $(Mg_{0.5}Fe_{0.5}^{3+})(Fe_{0.5}^{3+}Si_{0.5})O_3$ coexisting with wadsleyite and stishovite or bridgmanite 53 and stishovite. Because the Fe³⁺-rich phase forms within a much less Fe-rich bulk composition, it 54 could be found in oxidized natural lithologies. However, these studies did not observe the 55 structure of $(Mg_{0.5}Fe_{0.5}^{3+})(Fe_{0.5}^{3+}Si_{0.5})O_3$ in situ at high pressure and temperature. Identifying this 56 phase, its stability range, and physical properties is important to determining the mineralogy of 57 oxidized mantle and its impact on geophysics. 58

 $(Mg_{0.5}Fe_{0.5}^{3+})(Fe_{0.5}^{3+}Si_{0.5})O_3$ recovered from lower mantle pressures exhibits a structure 59 within the corundum family, a group of minerals with related structures and multiple possible 60 cation orderings including corundum Al₂O₃ and hematite Fe₂O₃ (space group $R\overline{3}c$), hemleyite 61 62 FeSiO₃ and ilmenite FeTiO₃ (space group $R\overline{3}$), LiNbO₃-type wangdaoite FeTiO₃ (space group R3c) (Navrotsky 1998; Dubrovinsky et al. 2009; Bindi et al. 2017; Xie et al. 2020), and an R3 63 modified corundum structure similar to the LiNbO₃-type structure (Koemets et al. 2023) (Figure 64 1). Both LiNbO₃-type and ilmenite-type structures have two octahedral cation sites with different 65 sizes, denoted as AO₆ (A site) and BO₆ (B site), respectively. Cation ordering as in LiNbO₃ 66 makes this structure approach a distorted perovskite, and thus promotes its transition to 67 bridgmanite (orthorhombic perovskite) with a very low energy barrier (Navrotsky 1998). The 68 synthesis and phase transition of LiNbO₃-type $(Mg_{0.5}, Fe_{0.5}^{3+}))(Si_{0.5}, Al_{0.5}^{3+})O_3$ has also been 69 reported (Liu et al. 2019; Zhu et al. 2020; Koemets et al. 2023). Fe³⁺ can simultaneously 70 substitute for Mg^{2+} and Si^{4+} in compositions along the $MgSiO_3$ -Fe₂O₃ join. In contemporary 71 experiments to this work, $(Mg_{0.5}Fe_{0.5}^{3+})(Fe_{0.5}^{3+}Si_{0.5})O_3$ was identified with the R3c LiNbO₃-type 72 structure (Chanyshev et al. 2023), but additional single-crystal diffraction suggests reassigning 73 this material to the R3 structure (Koemets et al. 2023). Analysis of natural akimotoite and 74 75 hemleyite in chondritic meteorites (Sharp et al. 1997; Tomioka and Fujino 1997) demonstrates incorporation of Fe and Al in the ilmenite-structured silicate up to at least 50% Fe²⁺ in 76 substitution for Mg²⁺ on the A site, above the solubility limit determined by experiment (Ito and 77 Yamada 1982). Pressure can drive cation reordering transitions between the ilmenite and 78 LiNbO₃-type structures (Ko and Prewitt 1988), and the closely-related structures may be difficult 79 to distinguish with diffraction. 80

but also for MgSiO₃ akimotoite, stable above ~18-22 GPa (Ishii et al. 2011; Kulka et al. 2020). Experimental observations could be consistent with Fe^{3+} -rich majorite garnet or stabilization of Fe³⁺-rich LiNbO₃-type silicate or bridgmanite at transition zone depths. In this study, we performed powder and single-crystal X-ray diffraction (XRD) measurements on Fe³⁺-rich (Mg_{0.46}, Fe³⁺_{0.53})(Si_{0.49}, Fe³⁺_{0.51})O₃ at ambient conditions and high pressures as well as firstprinciples calculations to reveal its crystal structure, compressibility, and phase transition mechanism to bridgmanite.

111 **2 Materials and Methods**

112 **2.1 Experimental methods**

Synthesis and compositional characterization of the Fe³⁺-rich starting material used in 113 this work is described in Liu et al. (2018) and Dorfman et al. (2020). Electron microprobe 114 analysis shows the sample is chemically homogeneous with a composition of 115 Mg_{0.46(2)}Fe_{1.04(1)}Si_{0.49(1)}O₃ (Liu et al. 2018), and conventional Mössbauer spectroscopy is 116 consistent with 100% Fe³⁺/total Fe (Dorfman et al. 2020). Hence, the stoichiometric chemical 117 formula of the sample is determined to be $(Mg_{0.46}, Fe_{0.53}^{3+})(Si_{0.49}, Fe_{0.51}^{3+})O_3$. Crystals used in 118 single-crystal diffraction measurements were $\sim 200 \times 200 \times 200 \ \mu\text{m}^3$, while polycrystalline 119 aggregates with few-um grain size were used for powder diffraction measurements. 120

Single-crystal X-ray diffraction (XRD) was carried out at ambient conditions at the 121 GSECARS facility at APS, Argonne National Laboratory, in station 13BM-C. A silicon (311) 122 monochromator was used to select X-rays at 28.6 keV (0.434 Å) with 1 eV bandwidth. 123 Kirkpatrick-Baez mirrors focused the beam to vertical \times horizontal focus spot size of 15 μ m \times 15 124 µm, measured as full width at half maximum (FWHM). The MAR165 Charge Coupled Device 125 126 (CCD) detector (Rayonix) was placed about 200 mm away from the sample. LaB₆ powder standard was used to calibrate the distance and orientation of the detector. A $\sim 200 \times 200 \times 200$ 127 μm^3 crystal of $(Mg_{0.46}Fe_{0.53}^{3+})(Si_{0.49},Fe_{0.51}^{3+})O_3$ was mounted onto a polymer micromesh sample 128 129 holder (MiTeGen) for room pressure measurement. The sample was centered at the axis of rotation of the diffractometer and aligned with an optical microscope. At room pressure, a series 130 of 10° wide segment rotation exposure covered angular range from $\varphi = -90^{\circ}$ to 90°, followed by a 131 series of step φ -exposures, each covering 1° scan width. The typical exposure time was 1s/°. At 132

233 zero diffractometer position, the φ scan rotation axis for the 13BM-C diffractometer is in the 234 horizontal plane of the instrument, and is perpendicular to the incident X-ray direction. The 235 diffraction images were analyzed using the GSEADA/RSV software package (Dera et al. 2013). 236 SHELXL software was used for refinement (Sheldrick 2015). We used isotropic atomic 237 displacement parameters (U_{iso}) for all atoms due to the lack of independent reflections.

A symmetric diamond anvil cell (DAC) with 300-um flat diamonds was used for high-138 pressure experiments at ambient temperature. A 250-µm thick rhenium gasket was pre-indented 139 to $\sim 30 \,\mu\text{m}$, and a hole with diameter of 150 μm was drilled in the center using the laser drilling 140 system at HPCAT (Sector 16) of the Advanced Photon Source (APS), Argonne National 141 Laboratory (ANL) (Hrubiak et al. 2015). A polycrystalline sample aggregate sized $\sim 20 \times 20 \times 7$ 142 μ m³ was loaded into the sample chamber, and then Ne was loaded as a hydrostatic pressure 143 medium using the COMPRES/GSECARS gas-loading system (Rivers et al. 2008). Au powder 144 was spread on top of the sample serving as pressure standard with minimal pressure gradient 145 between sample and Au (Liu et al. 2018). Pressure was calculated from the Au (111) peak using 146 147 the equation of state (Fei et al. 2007).

148 The crystal structure during compression in the DAC was determined by angle-dispersive 149 synchrotron XRD measurements performed at beamline 13-BM-C of the APS, ANL with beam 150 characteristics and detector position calibration as described above. On compression at intervals 151 of 1-2 GPa, XRD images of the samples were recorded for an exposure time of 60 s. The XRD 152 images were integrated using the software DIOPTAS (Prescher and Prakapenka 2015). Crystal structures were examined using full spectrum Le Bail fitting implemented in the EXPGUI/GSAS 153 software package (Toby 2001), and the unit cell parameters were extracted based on five 154 155 diffraction lines (012, 104, 110, 113, 024, 116) using the program PDIndexer (Seto et al. 2010).

156 **2.3 First-principles calculations of the phase transition pathway**

To determine the effects of compositional and structural differences between MgSiO₃ and (Mg_{0.5}Fe_{0.5})(Fe_{0.5}Si_{0.5})O₃ on the phase transition path and energy barrier for formation of bridgmanite, we performed calculations using the stochastic surface walking (SSW) method integrated with density functional theory (DFT). SSW has successfully been used to predict the low-energy pathways of crystal phase transitions (e.g., Zhu et al. 2019). Calculations employed the Vienna ab initio simulation package (VASP) for plane wave DFT. Electron-ion interactions

for all atoms were represented in VASP using the projector augmented wave (PAW) scheme. 163 164 The exchange-correlation functional is described by the generalized gradient approximation in the Perdew-Burke-Ernzerhof parameterization. The pathway sampling was carried out in a 20-165 atom (4 MgSiO₃ units per cell) lattice for akimotoite, LiNbO₃-type phase, and bridgmanite. 166 Through SSW sampling, a large set ($\sim 10^2$) of initial/final state pairs was collected at 24 GPa. TS 167 was located using double-ended surface walking. The lowest energy pathway was found by 168 sorting the heights of computed energy barriers. Then, the lowest candidate pathway was refined 169 170 by solid-state NEB (ssNEB) method. In order to speed up the sampling, the Monkhorst-Pack kpoint mesh of $(4 \times 4 \times 4)$ set for sampling and energy barrier scan is 2 x 2 x 2, while for barrier 171 172 refinement the Monkhorst-Pack k-point mesh is set to 4 x 4 x 4. The kinetic energy plane wave cutoff is 500 eV. For all the structures, both lattice and atomic positions were fully optimized 173 until the maximal stress component is below 0.1 GPa and the maximal force component below 174 0.01 eV/Å. 175

176 **3 Results and discussion**

177 **3.1.** LiNbO₃-structured (Mg_{0.5}Fe_{0.5})(Fe_{0.5}Si_{0.5})O₃

At ambient conditions, single crystal and powder XRD indicate that 178 (Mg_{0.5}Fe_{0.5})(Fe_{0.5}Si_{0.5})O₃ recovered from synthesis at 24 GPa and 1873 K adopts the LiNbO₃-179 type structure (Figure 2). We attempted to fit each dataset using the $R\overline{3}$ ilmenite-type structure, 180 181 R3c LiNbO₃-type structure, and corundum-derivative R3 structure proposed by (Koemets et al. 2023) based on contemporaneous experiments. The $R\overline{3}$ ilmenite-type structure and R3c differ 182 only in the ordering of the two cation sites (Supplementary Figure S1). R3 is nearly identical to 183 R3c but has lower symmetry. For the single-crystal XRD data, fits to the $R\overline{3}$ ilmenite and R3 184 structures do not converge. Additional peaks expected for the $R\overline{3}$ ilmenite structure are not 185 present. Due to the group-subgroup relationship between the R3 and R3c structures, it is possible 186 to describe the observed peaks with the R3 structure, and failure to converge may be due to the 187 higher number of degrees of freedom in the fit and completeness of the dataset. The fit to the R3c 188 LiNbO₃-type structure converges with R1-value of 7.11% and goodness of fit 1.423. Refinement 189 190 details, fractional coordinates and atomic displacement parameters are given in Supplementary Tables S1 and S2. Powder diffraction peaks are also consistent with R3c LiNbO₃-type structure. 191

This is the peer-reviewed, final accepted version for American Mineralogist, published by the Mineralogical Society of America. The published version is subject to change. 194 **Figure 2**. Single-crystal and powder diffraction observations (λ =0.434 Å) and fits for synthetic $(Mg_{0.46}Fe_{0.53}^{3+})(Si_{0.49}Fe_{0.51}^{3+})O_3$ at 0 GPa and 300 K. (a-b) Single-crystal X-ray diffraction pattern 195 viewed along (1 0 0) direction with peaks identified corresponding to the hexagonal R3c crystal 196 structure. The Mg/Fe and Si/Fe octahedra are represented by red and blue boxes, respectively. 197 Unit cell parameters obtained from this fit are a=4.9496(5) and c=13.3138(19), and V=282.47(6). 198 (c) Le Bail fitting applied to background-subtracted powder X-ray diffraction pattern: red solid 199 curve represents the refined profile, and green and orange vertical ticks indicate the LiNbO₃-type 200 structure and Au, respectively. Refined unit cell parameters are a = 4.950(5) Å, c = 13.323(2) Å, 201 and $V = 282.8(6) \text{ Å}^3$. 202

203 The ratio of c and a lattice parameters for the $(Mg_{0.5}Fe_{0.5})(Fe_{0.5}Si_{0.5})O_3$ is also more consistent with previous observations of LiNbO₃-type compounds than ilmenites. Refined lattice 204 parameters for $(Mg_{0.5}Fe_{0.5})(Fe_{0.5}Si_{0.5})O_3$ at 1 bar yield c/a ratio of 2.69 in both this study and 205 (Koemets et al. 2023). This value is near the upper end of the 2.61–2.70 range reported for 206 silicate, titanate, niobate, stannate, and other compounds with LiNbO₃-type ordering 207 (Leinenweber et al. 1995; Linton et al. 1999; Aimi et al. 2011) and lower than the 2.74–2.94 208

192

range reported for ilmenite-type ordering (Wechsler and Prewitt 1984; Kumada et al. 1990; 209 Baraton et al. 1994). Among ilmenite-structured silicates, $R\overline{3}$ MgSiO₃ akimotoite exhibits a c/a210 ratio of 2.87 and the ratio for $R\overline{3}$ FeSiO₃ hemleyite is 2.88 (Bindi et al. 2017). For Fe³⁺- and Al³⁺-211 bearing $(Mg_{0.5}Fe_{0.5})(Al_{0.5}Si_{0.5})O_3$, the c/a ratio is much lower at 2.65-2.67 and diffraction was 212 consistent with the LiNbO₃-type structure (Zhu et al. 2020; Koemets et al. 2023). The charge-213 coupled substitution of Fe^{3+} , $Mg_A^{2+} + Si_B^{4+} = Fe_A^{3+} + Fe_B^{3+}$, distributes Fe^{3+} evenly between the 214 AO₆ and BO₆ octahedra and effectively homogenizes these two sites. Fe³⁺-rich silicates are thus 215 close to the stability boundary between these two similar structures. 216

LiNbO₃-type (LN) $(Mg_{0.5}Fe_{0.5})(Fe_{0.5}Si_{0.5})O_3$ (50% hematite, 50% enstatite, called Hem50 hereafter) diffraction peaks are observed from 1 bar to 18.3(1) GPa at 300 K. XRD patterns of sample assemblages showed diffraction peaks from Hem50-LN, Au calibrant, and Ne medium (Supplementary Fig. S2). We observe no evidence of peak splitting, broadening, dissociation or transition of the LN structure up to 18.3(1) GPa.

222 **3.2. Equation of state**

The compression properties of Hem50-LN were obtained based on volumetric 223 compression measurements from 0 to 18.3(1) GPa (Supplementary Table S3, Figure 3). 224 Pressure-volume (P-V) data for Hem50-LN were fit to a 2nd-order Birch-Murnaghan equation of 225 state (BM-EoS). Resulting parameters are listed with literature values in Supplementary Table 226 S4. The slope of normalized stress-Eulerian strain (*F-f*) fitting is flat (Supplementary Figure S3), 227 supporting the validity of fixing K'_0 to 4. The V_0 for Hem50- LN is consistent with 50% linear 228 mixing between that of MgSiO₃ akimotoite (Wang et al. 2004) and Fe₂O₃ hematite (Bykova et al. 229 2016), although the crystal structures of the end-members are different. Observed volumes are 230 consistent with measurements obtained by Koemets et al. (2023), although they do not report 231 equation of state for the modified corundum structure for this composition. K_0 and K'_0 of MgSiO₃ 232 233 akimotoite have recently been constrained by Brillouin spectroscopy, ultrasonic, powder XRD measurements (Wang et al. 2004; Zhou et al. 2014; Siersch et al. 2021) and theoretical 234 calculations (Hao et al. 2019) to range between 205-210 GPa and 4.2-4.8, respectively. 235 Comparison between Hem50-LN and MgSiO₃ akimotoite indicates incorporation of Fe³⁺ through 236 substitution of $(Mg^{2+}+Si^{4+})$ on both A-site and B-site decreases the incompressibility of $MgSiO_3$ 237 akimotoite (Figure 3). The equation of state parameters of FeSiO₃ akimotoite compiled by 238

- 239 Stixrude and Lithgow-Bertelloni (2012) show a similar increase in K_0 compared to due to
- 240 incorporation of Fe^{2+} on A-site.

Figure 3. *P-V* plot for Hem50-LN, MgSiO₃ akimotoite (Wang et al. 2004), and Fe₂O₃ hematite (Bykova et al. 2016).

244 **3.3. Transition to perovskite-type structure**

241

At pressures higher than 18.3 GPa, new peaks corresponding to orthorhombic 245 246 bridgmanite (space group *Pnma*, hereafter Hem50-Bdg) gradually replace Hem50-LN (Figure 4). Clear signatures of the transition include the disappearance of the Hem50-LN (104) peak at 2θ 247 around 9.7° and increasing intensity of the Hem50-Bdg (112) peak at 2θ around 10.1° (Figure 4). 248 The Hem50-LN to Hem50-Bdg polymorphic transition was completed at 24.7(1) GPa. Full-249 250 profile Le Bail refinement of XRD pattern at 18.3 compared to the pattern at 24.7 GPa confirms the Hem50 LN-to-Bdg transition and pressure range. In conjunction with previous reported 300 251 252 K equation of state parameters of Hem50-Bdg, MgSiO₃ Aki and Bdg, we can calculate that the unit-cell volume decreases 3.5% across Hem50-LN to Bdg transition at 20 GPa. This contrast is 253 254 relatively smaller than the volume contrast of 5.9% across MgSiO₃ Aki and Bdg transition at 24 GPa. 255

Figure 4. Representative powder X-ray diffraction patterns of $(Mg_{0.46}, Fe_{0.53}^{3+})(Si_{0.49}, Fe_{0.51}^{3+})O_3$ at 18.3 - 24.7 GPa and 300 K, which show a phase transition from LiNbO₃-type structure to bridgmanite. Le Bail fitting is applied to interpret the pattern at 18.3 GPa: The red solid curve represents the refined profile, the gray curve represents misfit, and the vertical ticks represent LiNbO₃-type structure (green), Au (orange) and Ne (blue), respectively. At 24.7 GPa, the vertical ticks represent bridgmanite (black), Au (orange) and Ne (blue). The wavelength of the incident X-ray beam is 0.434 Å.

The transition from Hem50-LN to Hem50-Bdg occurred at 300 K without heating, which implies a low kinetic barrier between the two Fe^{3+} -rich phases along the MgSiO₃-Fe₂O₃ join. In contrast to the observed low kinetic energy barrier between Hem50-LN to Hem50-Bdg, the MgSiO₃ Aki – Bdg transition has been documented to require high temperature to overcome a high energy barrier (Ono et al. 2001). However, the LiNbO₃-type structure transforms to orthorhombic perovskite at room temperature on compression and the reverse on decompression for several compositions including (Mg,Mn,Fe,Zn)TiO₃ (Ross et al. 1989; Linton et al. 1997;

Inaguma et al. 2014; Akaogi et al. 2017), (Mg_{0.37}Fe_{0.22}Ca_{0.16}Mn_{0.01}Al_{0.25})(Al_{0.25}Si_{0.75})O₃ 271 (Funamori et al. 1997), and $(Mg_{0.5}, Fe_{0.5}^{3+}))(Si_{0.5}, Al_{0.5}^{3+})O_3$ (Zhu et al. 2020; Koemets et al. 2023). 272 273 The favorable kinetics of this transition is attributed to the ordering of cations in the LiNbO₃type structure that matches the perovskite ordering (Ross et al. 1989) and further promoted by 274 interchangeable ions on both cation sites. The octahedral (Fe³⁺, Si) site can rotate to form the 275 BO₆ octahedral network of the perovskite structure without breaking bonds (Megaw 1968). In 276 addition, for $(Mg_{0.5}, Fe_{0.5}^{3+})(Si_{0.5}, Fe_{0.5}^{3+})O_3 LN$, Fe^{3+} ions in either A or B sites can become Fe^{3+} in 277 either A or B sites in $(Mg_{0.5}, Fe_{0.5}^{3+}))(Si_{0.5}, Fe_{0.5}^{3+})O_3$ -bridgmanite, facilitating rearrangement of 278 sites without diffusing atoms during the phase transition. Thus, MgSiO₃ akimotoite and 279 $(Mg_{0.5}, Fe_{0.5}^{3+})(Si_{0.5}, Fe_{0.5}^{3+})O_3$ LN have different atom-to-atom correspondence pathways, and 280 consequently, more energy is needed to transform the akimotoite to correctly A/B sorted 281 282 bridgmanite.

We confirm the phase transition mechanism of Hem50-LN to Hem50-Bdg and the effects 283 of incorporation of Fe³⁺ on the energy barrier via theoretical simulations. We investigated the 284 structural transformation between Hem50-LN to Hem50-Bdg and MgSiO₃ Aki to Bdg, and 285 identified their lowest energy pathways, respectively (Figure 5). The mechanism of the 286 transformation between these related structures (Figure S1) is octahedral tilting. The enthalpy 287 barrier of the Hem50-LN to Hem50-Bdg transition is 0.19 eV/formula unit (f.u.) (18.33 KJ/mol), 288 289 which is only 14% of the 1.36 eV/f.u (131.22 KJ/mol) barrier for Fe-free Aki to Bdg transition. 290 The low enthalpy barrier between Hem50-LN to Hem50-Bdg explains our observation that the 291 transition thus can proceed even at ambient temperature. As a comparison, the activation energy for post-spinel transformation in Mg₂SiO₄ was estimated as 355 KJ/mol (Kubo et al. 2002a), 292 293 which requires overpressure of more than ~ 1 GPa at the transformation at 700 km depth in cold slabs. Growth of majoritic garnet (van Mierlo et al. 2013) and transformation from garnet to 294 bridgmanite (Kubo et al. 2002b) have also been argued to be delayed by kinetics in cold slabs. In 295 contrast, the ilmenite/ LiNbO3-type structure to Bdg transition would be more kinetically-296 297 favorable than the post-spinel or post-garnet transition.

298

The transition from LN-type phase to Bdg observed for our Fe³⁺-rich composition started 303 on compression between 18.3-19.7 GPa at 300 K. The onset of the transition is similar to the 18 304 GPa transition observed for LN-type $(Mg_{0.5}, Fe_{0.5}^{3+})(Si_{0.5}, Al_{0.5})O_3$ powder (Zhu et al. 2020). 305 However, experiments on single crystals of LN-type (Mg_{0.5},Fe³⁺_{0.5})(Si_{0.5},Al_{0.5})O₃ and modified 306 corundum R3 structure of $(Mg_{0.5}, Fe_{0.5}^{3+})(Si_{0.5}, Fe_{0.5}^{3+})O_3$ indicate transitions to Bdg or a novel 307 double perovskite at lower pressures, 8(2) and 12(2) GPa respectively (Koemets et al. 2023). The 308 309 difference in the observed transition pressures could be due to structure/compositional difference between the samples or differences in stress conditions in single crystal vs. powder (although all 310 studies employed neon quasi-hydrostatic pressure-transmitting medium). This difference in 311 transition conditions could also indicate the metastability of the LN-type phase. If hysteresis is 312 observed in the transition, the conditions at which the Gibbs free energy of the bridgmanite phase 313 becomes lower than the LN-type phase, whether or not this is the minimum energy (equilibrium) 314 315 state, should be between the minimum observed transition pressure on compression and 316 maximum transition pressure on decompression.

If 12(2) GPa is an upper bound on the LN or modified corundum *R*3 structure to (single or double) perovskite transition, this would be consistent with crystallization as perovskite-type phase at 15-27 GPa in all experiments by Wang et al. (2021), Chanyshev et al. (2023), and Koemets et al. (2023) and transformation to the *R*3c or *R*3 structure on decompression. These studies do not have in-situ characterization to confirm the structure formed at 15-27 GPa. Because synthesis experiments performed in the bridgmanite stability field yielded LiNbO₃-type

phase upon quenching to ambient pressures, we infer that the reverse transition during decompression proceeds without heating as well (Liu et al. 2018; Wang et al. 2021). In addition, if the Clapeyron slope of the conditions of the LN-Bdg transition is negative (like the Aki-Bdg transition), the LN-Bdg transition could occur at even lower pressures at high temperatures. These results point to Fe^{3+} stabilizing the perovskite structure within the Earth's transition zone.

328 4 Geophysical implications

Differences in the stability of corundum-family and bridgmanite structures due to 329 330 composition may impact the dynamics of subducting slabs. MgSiO₃ akimotoite in subducting slabs is thought to impede subduction at 660 km depth due to the Aki-Bdg transition with a 331 negative Clapeyron slope and low density (e.g. Chanyshev et al. 2022). Incorporation of up to 332 $\sim 10\%$ Fe²⁺SiO₃ in ilmenite-structured akimotoite was observed to have no effect on the transition 333 334 from akimotoite to bridgmanite, or possibly slightly increase the transition pressure based on observed compositions of coexisting phases (Ito and Yamada 1982), further impeding 335 subduction. In contrast, in an oxidized Fe-bearing system, dense Fe^{3+} -bearing bridgmanite may 336 be stable within the MgSiO₃ akimotoite stability field. Crystallization of this dense phase within 337 338 oxidized subducting lithosphere at transition zone pressures may facilitate subduction.

Whether phase transitions from akimotoite or spinel to bridgmanite result in a seismic 339 discontinuity depends on the depth range of coexistence of low-pressure and high-pressure 340 341 phase. Incorporation of Al in MgSiO₃ bridgmanite is predicted to broaden the transition pressure range by ~1 GPa, and increase the Aki-Bdg transition pressure by ~2-3 GPa along a cold slab 342 geotherm (Ita and Stixrude 1992; Vacher et al. 1998; Akaogi et al. 2002). For compositions 343 enriched in Al³⁺, this breadth suggests that a transition from the Aki to Bdg would not be 344 observable globally as a sharp seismic discontinuity. The 660-km discontinuity can be explained 345 by the post-spinel transition in both pyrolite (Ishii et al. 2011) and harzburgite (Irifune and 346 347 Ringwood 1987) not only due to its steep Clapeyron slope, but also the extremely narrow transition pressure interval (Ito and Takahashi 1989; Ishii et al. 2019). In the MgSiO₃-Fe₂O₃ 348 system investigated by (Wang et al. 2021; Chanyshev et al. 2023), most of the Fe₂O₃ component 349 partitions into the Fe³⁺-rich phase, leaving relatively Fe³⁺-depleted spinel and bridgmanite. This 350 351 partitioning can be expected to further sharpen the post-spinel phase boundary at 660 km. Because the LiNbO₃-type phase does not appear to be stable and bridgmanite would replace 352

akimotoite, no discontinuity would be observed associated with the akimotoite-bridgmanite
 transition in oxidized Fe-bearing mantle.

The stability of Fe^{3+} -rich bridgmanite in the transition zone depends on the presence of 355 sufficient iron and high oxygen fugacity. Mantle lithologies exhibit widely ranging oxygen 356 fugacity (Cottrell et al. 2021), and upwelling plumes also may be relatively oxidized 357 (Moussallam et al. 2019). Self-disproportionation of Fe^{2+} may elevate the concentration of Fe^{3+} 358 in the transition zone, as in the lower mantle for the mineral bridgmanite (Frost et al. 2004; 359 Rohrbach et al. 2007; Chanyshev et al. 2023). As a minor phase, Fe^{3+} -bearing bridgmanite in the 360 transition zone would not dominate seismic properties, but could have a significant effect on 361 density, composition, and seismic properties of the overall phase assemblage. 362

The LiNbO₃-type structure has also been observed in natural materials that have been 363 shocked to high pressures during planetary impacts and inferred to represent back-transformation 364 from the perovskite structure. LiNbO3-structured FeTiO3 now named wangdaoite, was 365 documented in the Ries impact crater (Dubrovinsky et al. 2009) and in the Suizhou chondritic 366 meteorite (Xie et al. 2020). In these samples, coexisting minerals suggest shock pressures 367 estimated in the range 16-28 GPa, corresponding to the FeTiO₃ perovskite stability field. Shock 368 veins in chondrites also contain $R\overline{3}$ FeSiO₃ hemleyite (Bindi et al. 2017) and MgSiO₃ akimotoite 369 (Tschauner et al. 2018) and Pnma FeSiO₃ hiroseite (Bindi et al. 2020) and MgSiO₃ bridgmanite 370 (Tschauner et al. 2014). In contrast to natural hemleyite, which was reported to contain no 371 significant ferric iron, natural hiroseite was observed with Fe³⁺/Fe total ~19%, supporting the 372 importance of crystal chemistry of Fe^{3+} in perovskites. However, interpretation of $R\overline{3}c$ hematite 373 in meteorites is complicated by the many mechanisms by which this phase forms, including 374 weathering and low-pressure, high-temperature decomposition of silicates (e.g. Kuchka et al. 375 2017). The results of this work provide constraints on interpreting intermediate MgSiO₃-Fe₂O₃ 376 phases transformed during shock impacts. 377

378 **5** Conclusions

We performed high-pressure XRD measurements on synthetic LiNbO₃-type ($Mg_{0.46}, Fe_{0.53}^{3+}$)(Si_{0.49}, Fe_{0.51}^{3+})O_3 (Hem50-LN), and we observed the Hem50-LN to Bdg transition occurring between 18.3 GPa -24.7 GPa at 300 K. We investigated the phase transition mechanism of akimotoite and LiNbO₃-structured phases to bridgmanite with compositions of

both MgSiO₃ and (Mg_{0.5},Fe³⁺_{0.5})(Si_{0.5}, Fe³⁺_{0.5})O₃ via first-principles calculation and determined that accommodating Fe in LN-phase results in a lowered kinetic energy to transform to bridgmanite relative to transforming to bridgmanite from akimotoite. Our experiments and calculations confirm that accommodating Fe³⁺ in LN can significantly decrease the kinetic energy barrier to crystallize bridgmanite. Due to enrichment of Fe³⁺, this dense phase may play an important role in slab dynamics and localized geochemical anomalies.
