ABSTRACT

To better understand the transport of Mo and W in granitic melts and the formation mechanism of porphyry ore deposits, we have investigated the diffusivities of Mo and W in granitic melts with 0.04–5.1 wt% H₂O at 1000–1600 °C and 1 GPa using a diffusion couple approach and a Mo saturation approach with Mo sheet serving as the source. The Mo and W diffusivities obtained from diffusion profiles measured by LA-ICP-MS can be described as:

$$\begin{aligned}D_{\text{Mo,anhy}} &= 10^{-1.47 \pm 0.73} \exp[-(387 \pm 25)/RT], \\D_{\text{W,anhy}} &= 10^{-1.28 \pm 1.05} \exp[-(396 \pm 35)/RT], \\D_{\text{Mo,2.7wt\%H}_2\text{O}} &= 10^{-5.37 \pm 0.52} \exp[-(211 \pm 18)/RT], \\D_{\text{Mo,5.1wt\%H}_2\text{O}} &= 10^{-6.87 \pm 0.69} \exp[-(133 \pm 20)/RT],\end{aligned}$$

where D is diffusivity in m²/s (with the subscripts denoting water contents and “anhy” representing nominally anhydrous melt), R is the gas constant, T is the temperature in K, and the activation energies in the exponential are in kJ/mol. When the influence of H₂O is incorporated, Mo diffusivity in granitic melts with <5.1 wt% H₂O can be modeled as:

$$\log D_{\text{Mo}} = -(1.94 \pm 1.58) - (0.87 \pm 0.36)w - [(19341 \pm 2784) - (2312 \pm 620)w]/T$$

where w is H₂O content in the melt in wt%. The diffusion behavior (low diffusivities, high activation energies, and strong H₂O effects) of Mo and W indicates that they exist and diffuse in the melt in the form of hexavalent cations. Their low diffusivities imply that the bulk concentrations of Mo and W in exsolved hydrothermal fluid and those in the melt are probably not in equilibrium. However, because of the large fluid-melt partition coefficients of Mo and W, they can still be enriched in the hydrothermal fluid, although to a lesser extent than equilibrium partitioning would allow. Slow Mo and W diffusion can be a significant rate-limiting step for the formation of porphyry Mo/W deposits.
