ABSTRACT

High-angle annular dark-field scanning transmission electron microscopy is a powerful *Z*-contrast technique able to depict the structural motifs in Pb-(Bi-Sb)-sulfosalts. Using two homologs from the kobellite homologous series, a group of “chessboard derivative structures,” represented by Bi-, and Sb-rich pairs of natural phases (the kobellite-tintinaite isotypic series and giessenite-izoklakeite homeotypic series), we visualize the slabs underpinning crystal structural modularity for the $N = 2$ homolog kobellite and the $N = 4$ homolog, in this case a Bi-rich izoklakeite [$\text{Sb}/(\text{Sb}+\text{Bi}) = 0.35$]. The homolog number, N , can be readily calculated as $N = n_1/6 - 1$ and $N = n_2/4$, where n_1 and n_2 are the numbers of atoms in the PbS- and SnS-motifs, respectively. Atom-scale imaging of thinned foils extracted in situ from samples for which compositional data are available also reveals syntactic unit-cell scale intergrowths on [001] zone axis with $a_{\text{kobellite}} \parallel b_{\text{izoklakeite}}$. These are as small as half-unit cells of $b_{\text{izoklakeite}}$ and one-unit cell $a_{\text{kobellite}}$. Replacement relationships are also observed as irregular slabs of kobellite “intruding” into izoklakeite. Both banded and irregular intergrowths account for the compositional fields measured at the micrometer scale.

Keywords: HAADF STEM, chessboard structures, izoklakeite, kobellite
