ABSTRACT

Magmatic oxygen fugacity (f_{O_2}) exerts a primary control on the discrete vanadium (V) valence states that will exist in quenched melts. Vanadium valence proxies for f_{O_2} , measured using X-ray absorption near-edge spectroscopy (XANES), can provide highly sensitive determinations of the redox conditions in basaltic melts. However, X-ray beam-induced changes in V speciation will introduce uncertainty in the calculated average V valence (V^*) that must be properly evaluated to make meaningful interpretations of the igneous evolution of the system. The study presented here showed that beam-induced modifications in V speciation are observed in silicate glasses that are dependent on the radiation dose rate used during analysis. Changes in V speciation are observed to be most pronounced at the highest flux density tested, 9.25×10^{11} ph/s/ μm^2 (photons per second per square micrometer), with rapid changes occurring in the first 200 s of analysis. The high-dose rate conditions result in changes in calculated V^* ~ 0.3 valence unit for the most oxidized glass analyzed ($V^* = 4.94$), which can correspond to ~ 0.5 log unit reduction in calculated f_{O_2} . However, at flux densities $\leq 1.13 \times 10^9$ ph/s/ μm^2 , measured changes in V^* were found to be < 0.03 for all standard glasses analyzed. The degree of reduction observed during analysis is also found to be progressively smaller as the initial V^* of the glass decreases, such that magmatic glasses with V^* values ≤ 3.7 show no statistically significant change in calculated valence during analysis at any flux density tested. For most terrestrial magmatic glasses, where V^* is found to be < 4 , beam-induced changes in V^* can be effectively minimized (< 0.04), within analytical uncertainty of the XAFS analysis, by limiting flux densities to be $\leq 1 \times 10^9$ ph/s/ μm^2 .
