ABSTRACT

Biotite solid-solutions are a significant H₂O reservoir in the lithosphere, and the assemblage Bt+Opx+Kfs+Qtz is commonly used to estimate $a_{\text{H}_2\text{O}}$ in high-grade metamorphic and magmatic rocks. Here we report experimental constraints on subsolidus mineral equilibria involving biotite and orthopyroxene in the system KAlO₂-MgO-FeO-SiO₂-H₂O-CO₂. Our experiments address the question of stability of biotite of a given X_{Fe} in the assemblage Bt+Qtz±Sa, or the stability of the assemblage Opx+Sa±Qtz. Clemens (1993) and Clemens et al. (1997) concluded that CO₂ has no effect other than to lower $a_{\text{H}_2\text{O}}$ and thereby raise the solidus T . Our data at $X_{\text{H}_2\text{O}}^{\text{fl}} < 1$ extend these conclusions to encompass Fe-bearing systems more similar to natural rocks. From a comparison of experimental data and calculated isopleths of biotite composition in the divariant assemblage Bt+Opx+Kfs+Qtz+fluid, it appears that phlogopite-annite solid-solutions must be significantly non-ideal (at $T < 800$ °C) or that enstatite-ferrosilite solid-solutions must have negative values for their Margules-type parameters. Ignoring these factors would result in any calculated $a_{\text{H}_2\text{O}}$ values being too low. Although various models allow us to estimate $X_{\text{H}_2\text{O}}$ in H₂O-CO₂ fluids, we are still unable to use biotite equilibria to estimate $a_{\text{H}_2\text{O}}$ accurately during high-grade metamorphism and magma crystallization. We also consider qualitatively the effects Fe-Mg biotite solid-solution on partial melting equilibria in fluid-poor (rock-dominated) systems in which hydration-dehydration reactions control the fluid composition.
